

EXAMINATION OF ABNORMAL DOLICHOL METABOLISM
IN INFANTILE BATTEN DISEASE CAUSED BY
PALMITOYL PROTEIN THIOESTERASE-1 (PPT1) DEFICIENCY

APPROVED BY SUPERVISORY COMMITTEE

Committee Chairperson's Name _____
Mark A. Lehrman, Ph.D.
Professor of Pharmacology

Committee Member (Advisor)'s Name _____
Sandra L. Hofmann, M.D., Ph.D.
Professor of Internal Medicine and Molecular Genetics

Committee Member's Name _____
Joel M. Goodman, Ph.D.
Professor of Pharmacology

Committee Member's Name _____
Paul C. Sternweis, Ph.D.
Professor of Pharmacology

DEDICATION

To our Heavenly Father, who created me to glorify His name.

To my baby sister, who is in Heaven in peace.

To my parents, who always believe in me and support me.

To my wife Judy and my children Timothy and Rachel, who are inspirations of my life.

EXAMINATION OF ABNORMAL DOLICHOL METABOLISM
IN INFANTILE BATTEN DISEASE CAUSED BY
PALMITOYL PROTEIN THIOESTERASE-1 (PPT1) DEFICIENCY

ACKNOWLEDGEMENTS

There are numerous people who have helped me during my long journey here at UT Southwestern. First of all, I would like to thank my mentor, Dr. Sandy Hofmann, for her guidance and advice on my dissertation work. I have learned many things from her throughout the years in her lab. She taught me how to become a good scientist and how to think like a good scientist. I am also grateful to my dissertation committee members, Dr. Mark Lehrman, Dr. Joel Goodman and Dr. Paul Sternweis for their invaluable advice and support.

I was fortunate to have so many good friends and colleagues who believed in me. I would like to thank Hofmann lab members, Drs. Laura Lu, Amit Das, Praveena Gupta, Andrea Qiao and Hasige Sathish, for their advice, assistance, encouragement and friendship. I am particularly grateful to Dr. Ningguo Gao in Lehrman's lab who has helped me to finish my last project. I also would like to thank our collaborators, Dr. Skip Waechter and Dr. Jeff Rush at University of Kentucky, who allowed me to visit their lab to perform experiments.

I would like to thank Ms. Carla Childers, Cell Regulation Program Coordinator, for her administrative assistance during my years of graduate school.

Finally, I would like to thank my wonderful parents. They always have confidence in me and support me, and have never doubted that I would finish this journey. My wife Judy and my children, Timothy and Rachel, have stood beside me during this long journey. They have been my motivation and inspiration.

ABSTRACT

The neuronal ceroid lipofuscinosis (NCLs, also known collectively as Batten disease) are a group of lysosomal storage disorders characterized by the accumulation of autofluorescent storage material in the brain. Although a number of genes underlying different forms of NCL have been cloned, the underlying mechanism for the neurodegeneration is still unknown. The most severe form of NCL (infantile NCL) is caused by mutations in the *CLN1/PPT1* gene, which encodes a soluble lysosomal hydrolase (palmitoyl protein thioesterase-1) that removes fatty acids from lipid modified proteins in the lysosome. It has been postulated that abnormal dolichol metabolism might be involved in NCL pathogenesis because high levels of dolichol phosphate (Dol-P) and lipid linked

oligosaccharides (LLOs) accumulate in NCL patients including infantile NCL. Here, a possible relationship between fatty acid and dolichol metabolism in the neuropathogenesis of NCL has been explored by analyzing LLOs from mouse models of Batten disease and other non-NCL lysosomal storage diseases (LSDs), and by characterizing a unique fusion protein consisting of PPT1 and a dolichol metabolizing enzyme (DOLPP1) in *Schizosaccharomyces pombe*, which we named *pdf1* (for *ppt1-dolpp1 fusion1*).

To do this, first, I characterized *S. pombe pdf1* by ablating the *pdf1* gene and studying the function of each of the proteins (PPT1 and DOLPP1) independently. These results revealed that *PPT1* and *DOLPP1* may be co-regulated in lower organisms but the functional relationship in higher eukaryotes remains unclear.

To further explore the relationship between *PPT1* and *DOLPP1* in mammalian cells, I cloned the mammalian ortholog of *DOLPP1* and subsequently characterized the mouse Dolpp1p.

Finally, I characterized and analyzed LLOs in various mouse models of NCL by FACE (fluorophore assisted carbohydrate electrophoresis). It was shown that LLOs accumulated in PPT1-deficient mouse brain and the level of LLO accumulation was 14.5-fold higher as compared to wild type brain. Despite the striking accumulation of LLOs in PPT1-deficient brain compared to age-matched controls, I also found that the LLOs encompassed only 0.3% of the autofluorescent storage material by mass. Therefore, the abnormal dolichol catabolism is most likely a secondary phenotype to PPT1 deficiency during the pathogenesis of infantile Batten disease.

LIST OF DEFINITIONS

ANDS	7-amino-1, 3-naphthalenedisulfonic acid
bp	Base pair
cDNA	Complementary deoxyribonucleic acid sequence
CHO	Chinese hamster ovary
Ci	Curie
CoA	Coenzyme A
Cpm	Counts per minute
CPY	Carboxy peptidase Y
CV	Curvilinear profiles
Dol	Dolichol
Dol-P	Dolichol phosphate
Dol-P-P	Dolichol pyrophosphate
DOLPP	Dolichol pyrophosphate phosphatase
Dol-PP-OS	Dolichol pyrophosphoryl oligosaccharide
DTT	Dithiothreitol
ECL	Enhanced Chemiluminescence
EM	Electron microscopy
EMM	Edinburgh minimal media
Endo H	Endoglycosidase H
ER	Endoplasmic reticulum
EST	Expressed sequence tag
5'FOA	5-fluoroorotic acid
FACE	Fluorophore-assisted carbohydrate electrophoresis
FP	Fingerprint profiles
g	Standard earth gravitational unit
Glc	Glucose
GlcNAc	N-acetyl- <i>D</i> -glucosamine

GPI-anchor	Glucose phosphate inositol anchor
GROD	Granular osmophilic deposits
h	Hour
HEPES	N-[2-hydroxyethyl]piperazine-N'-[2-ethanesulfonic acid]
HPLC	High pressure liquid chromatography
IgG	Immunoglobulin G
kDa	Kilodalton
LLO	Lipid linked oligosaccharide
LSD	Lysosomal storage disease
M	Molar
Man	Mannose
ME	Malt extract
MeOH	Methanol
mCi	Millicurie
mg	Milligram
min	Minute
ml	Milliliter
mM	Millimolar
M _r	Relative mobility
μg	Microgram
μl	Microliter
μM	Micromolar
NADPH	Reduced nicotinamide adenine dinucleotide
NCL	Neuronal ceroid lipofuscinosis
ORF	Open reading frame
PA	Phosphatidic acid
PAS	Periodic acid-Schiff reagent
PCR	Polymerase chain reaction
PPT	Palmitoyl-protein thioesterase

PBS	Phosphate-buffered saline
Pmole	Picomole
RL	Rectilinear complexes
rpm	Revolutions per minute
s	Second
SDS	Sodium dodecylsulfate
SDS-PAGE	Sodium dodecylsulfate polyacrylamide gel electrophoresis
Tris	Tris(hydroxymethyl)aminomethane
TUNEL	Terminal dUTP nick end-labeling
YES	Yeast extract plus supplement

CHAPTER ONE

Introduction

1.1 Hypothesis

As is true of many lysosomal storage disorders, the mechanism whereby the underlying enzyme deficiency leads to organ pathology in NCL (neuronal ceroid lipofuscinosis) is poorly understood. The storage material (granular osmophilic deposits, GROD) accumulating in infantile NCL patients' brain and other peripheral tissues is heterogeneous and complex, largely defying attempts at characterization.

PPT1 deficiency is the underlying cause of infantile NCL (Vesa *et al.* 1995). PPT ortholog in *S. pombe* is a fusion gene with a partner gene, which is an ortholog of mouse *DOLPPI* that encodes dolichol pyrophosphate phosphatase-1 (Cho *et al.* 2004). Dolpp1p is an enzyme that is implicated in dolichol recycling during *N*-glycosylation process (Rush *et al.* 2002). Furthermore, there have been numerous reports that high level of dolichol phosphate and its oligosaccharide intermediates are accumulated in the brain tissue of NCL patients including infantile NCL (Keller *et al.* 1984; Hall *et al.* 1985; Hall *et al.* 1987; Hall *et al.* 1988; Hall *et al.* 1992). All of these observations have led me to the hypothesis that abnormal dolichol metabolism may be involved in the pathogenesis of infantile NCL.

Therefore, throughout the next three chapters of this dissertation, I will examine the function of *S. pombe* pdf1, an ortholog of *PPT1* in fission yeast, by exploring whether Ppt1p and Dolpp1p are functioning as a single polypeptide that physically interact with each other or two proteins that eventually separate to function independently of each other. I will also

investigate the possible link between these two proteins in mammalian cells by cloning and characterizing the mammalian ortholog of DOLPP1 from a mouse brain cDNA library. I will examine the subcellular localization of mammalian Dolpp1p to see whether these two proteins are able to physically interact in higher eukaryotic cells. Finally, I will analyze the accumulation of lipid linked oligosaccharides (LLOs) in infantile NCL using a PPT1 knockout mouse model, other mouse models of NCLs and non-NCL lysosomal storage disease (LSD) mouse models which cause neuronal degeneration.

1.2 Neuronal Ceroid Lipofuscinosis

1.2.1 History

The neuronal ceroid lipofuscinoses (NCL, also known collectively as Batten disease) are a group of progressive inherited neurodegenerative disorders of children characterized by the accumulation of autofluorescent inclusion bodies in the brain and other tissues (Mitchison et al. 2001; Hofmann 2002). In 1969, Zeman and Dyken first used the term ‘neuronal ceroid lipofuscinosis’ to distinguish the group of diseases, now known as NCL, from the gangliosidoses (Zeman et al. 1969). The historical description of the disorder was illustrated much earlier in the 19th century by Stengel (Stengel 1826) in a case report of four siblings who suffered blindness, epilepsy, and motor dysfunction (Wisniewski *et al.* 2001a).

The pathological assessments including electron microscopic (EM) studies on autopsy brain tissues from NCL patients have revealed unique pathological markers for different subtypes of NCL along with different ages of onset of symptoms. These four classical classifications are infantile, late-infantile, juvenile and adult NCLs. Each class of

NCL is represented by a unique pattern of lysosomal inclusion bodies including granular osmophilic deposits (GROD), curvilinear profiles (CV), fingerprint profiles (FP) and rectilinear complexes (RL), respectively (Wisniewski *et al.* 2001b).

In 1995, mutations in a lysosomal enzyme called palmitoyl protein thioesterase-1 were discovered to be the underlying cause of the infantile form of NCL (Vesa *et al.* 1995). Since the first gene (PPT1) was cloned for NCLs, rapid technical advances in molecular genetics and biochemistry allowed the identification of five more genes that are responsible for NCLs, demanding a new classification system. Therefore, a new gene designation (CLN) was introduced for NCLs including the four classical forms. To date, eight different forms of NCL are distinguished (CLN1 to CLN8) as summarized in Table 1.1.

CLN1/PPT1, CLN2/TPPI, CLN3 and CLN4 were assigned for the four classical forms of NCLs; infantile, late-infantile, juvenile and adult, respectively (Lerner *et al.* 1995; Vesa *et al.* 1995; Schrinier *et al.* 1996; Sharp *et al.* 1997; Sleat *et al.* 1997). CLN4 is a reserved gene designation for adult-onset autosomal dominant NCL; the genetic locus has not been mapped (Kufs 1925; Das *et al.* 1998). The locus for CLN7, which represents the Turkish variant of late-infantile NCL, also has not been mapped, and CLN7 may be an allelic variant of one of the NCLs (Ranta *et al.* 1999; Mitchell *et al.* 2001). CLN5, CLN6 and CLN8 represent Finnish variant late-infantile NCL, Gypsy/Indian late-infantile NCL and Northern epilepsy with mental retardation, respectively (Savukoski *et al.* 1994; Sharp *et al.* 1997; Savukoski *et al.* 1998; Ranta *et al.* 1999).

1.2.2 Dolichol in NCLs

Table 1.1 Classifications of NCLs

Gene	Form	Locus	Protein encoding	Characteristics	^{f,g}Ref.
CLN1	Infantile NCL	1p32	Palmitoyl protein thioesterase-1	Blindness Motor deterioration ^a GROD	
CLN2	Late-infantile NCL	11p15	Tripeptidyl peptidase-I	Seizures Motor deterioration ^b CV	
CLN3	Juvenile NCL	16p12	Lysosomal transmembrane protein	Visual loss and seizures Motor dysfunction ^c FP	
CLN4	Adult NCL	unknown	unknown	Myoclonic epilepsy Autosomal dominant Dementia, ^d RL / ^e Mixed	
CLN5	Finnish variant late-infantile NCL	13q22	Lysosomal transmembrane protein	Motor deterioration Visual loss	
CLN6	Gypsy/Indian late-infantile NCL	15q21-23	Putative transmembrane protein	Visual loss Seizures Motor	
CLN7	Turkish variant late-infantile NCL	unknown	unknown	Motor dysfunction Seizure

^{f,g}Ref: reviewed in (Elleder et al. 1999; Wisniewski et al. 2001a).

Ng Ying Kin *et al* reported significant amounts of dolichol in the storage material accumulating in human cerebral cortex from infantile, late-infantile and juvenile forms of NCL patients as compared to age-matched controls, implying possible defects in dolichol metabolism in NCL patients (Ng Ying Kin *et al.* 1983). Dolichols are α -saturated, long chain polyprenols with chain length of 14-21 isoprene units, as shown in Figure 1.1 (Schenk *et al.* 2001).

Figure 1.1 Structure of Dolichol

In the early 1960's dolichols were first described as a main component of unsaponifiable lipid in animal tissues during studies on the polyisoprenoid side chain of ubiquinone (Pennock *et al.* 1960). Dolichols are found in almost all membranes in eukaryotic cells and tissues, and the amount of dolichols varies from 5 to 150 $\mu\text{g/g}$ depending on tissue types in different animals (Valtersson *et al.* 1985).

Dolichol exists in three different forms of in the cell: free dolichol, dolichol esterified with fatty acids and phosphorylated dolichol (Hemming 1992). The phosphorylated dolichol (Dol-P) and its oligosaccharyl derivatives (Dol-PP-OS) play a key role as a lipid carrier during the biosynthesis of asparagine (N)-linked glycoproteins in the endoplasmic reticulum

(ER). Eukaryotic cells have a very small amount of Dol-P as compared to total dolichols and the pool size of Dol-P is rate-limiting in glycosylation reactions in the ER (Carson *et al.* 1981; Eggens *et al.* 1984). Free dolichols and esterified dolichols have been postulated to be involved in the modulation of membrane fluidity, stability and permeability (Valtersson *et al.* 1985; Wood *et al.* 1986; Monti *et al.* 1987).

Elevated levels of dolichol, however, have also been reported in brains of the elderly, suggesting dolichol accumulation as a marker of aging (Pullarkat *et al.* 1982). Dolichol levels in normal human brain increases more than 10-fold from 18 $\mu\text{g/g}$ (6-year-old) to 263 $\mu\text{g/g}$ (68-year-old), and a similar pattern of increase has also been seen in mouse and rat brain with age (Ng Ying Kin *et al.* 1983; Pullarkat *et al.* 1984). Later, the level of dolichol in Alzheimer patients ($384 \pm 90.7 \mu\text{g/g}$) has also shown to be increased significantly compared to age-matched control brains ($190 \pm 48.9 \mu\text{g/g}$), implicating accumulation of dolichol in NCLs as a secondary phenotype of aging (Ng Ying Kin *et al.* 1983; Wolfe *et al.* 1983). Therefore, further work is needed to explain the precise mechanism of dolichol accumulation during NCL pathogenesis and the aging process.

1.2.3 Phosphorylated dolichol (Dol-P) in NCLs

The most metabolically active form of dolichol in cells is phosphorylated dolichol (Dol-P) (Kornfeld *et al.* 1985). One striking observation from the pre-genomic era was abnormally high levels of total Dol-P (measured after hydrolysis of all Dol-P containing compounds) in brain tissue of all three childhood forms of NCL, adult NCL and canine NCL, reaching concentrations 10 to 20 fold higher than those of age-matched controls (Keller *et al.*

1984; Hall *et al.* 1985; Wolfe *et al.* 1988). Elevated Dol-P concentrations comparable to those of NCLs were, however, also shown in some of lysosomal storage diseases (LSDs) such as GM1 gangliosidosis and Niemann Pick's Type C disease (Wolfe *et al.* 1988; Hall *et al.* 1989; Schedin *et al.* 1995). It turned out that dolichol levels were also shown to increase in some of these LSDs such as aspartylglucosaminuria (AGU), mannosidosis, Sanfilippo B syndrome and GM1 gangliosidosis (Humaloja *et al.* 1991; Jokelainen *et al.* 1992; Sakakihara *et al.* 1994; Schedin *et al.* 1995). These observations in LSDs imply that the high level of dolichol and/or Dol-P accumulations in cerebral cortex might be a secondary phenotype of lysosomal dysfunction in neurodegenerative disorders.

Interestingly, HPLC analysis was performed to show that the bulk of the Dol-P found in the classical childhood NCL patients was present as dolichol pyrophosphoryl oligosaccharides (lipid-linked oligosaccharides, LLO) because periodic acid-Schiff reagent (PAS) staining had suggested that the storage material contains carbohydrate (Hall *et al.* 1985; Hall *et al.* 1987; Hall *et al.* 1988; Daniel *et al.* 1992; Hall *et al.* 1992). Furthermore, oligosaccharide structure analysis suggested that the LLO were derived from catabolic rather than synthetic intermediates. These studies were, however, limited by uncertainties as to the genetic diagnosis in the clinical specimens, the use of autopsy material, the paucity of samples available for analysis, and technical limitations imposed by more cumbersome analytical methods (Schedin *et al.* 1995).

Still, early efforts at characterization of the storage material in the NCLs have led to several observations that may be of value in understanding the underlying pathophysiology of these disorders and their potential relation to changes that occur with normal aging.

1.2.4 Infantile NCL

The most severe form among NCLs is infantile NCL, with age of onset of symptoms and premature death as early as age of 2-3 years (Vesa *et al.* 1995; Hofmann *et al.* 1997; Hofmann *et al.* 1999; Das *et al.* 2001). As described above, accumulation of granular osmophilic deposits (GROD) in the lysosomal storage material in patient's brain tissues is a hallmark of INCL (Das *et al.* 1998). Although INCL patients are found worldwide, the carrier frequency of one particular mutant allele is very high in the Finnish population, which is 1 in 70 (Vesa *et al.* 1995; Lu *et al.* 1996; Hofmann *et al.* 2001a). Affected Finnish infants are homozygous for a single missense mutation (A364T or R122W), and develop visual loss, speech and motor deterioration and uncontrollable seizures beginning at the age of 6-8 months. The neurodegeneration progresses with those symptoms, and affected children show flat electroencephalogram by the age of 3 (Das *et al.* 2001).

Unlike the patients in Finland, it has been shown by Das *et al.* that those INCL patients in the U.S. and Canada exhibit a clinically and molecularly more heterogeneous nature of the disorder. A total of 19 different mutations were identified, and the two nonsense mutations (R151X and T75P) accounted for 53 % of the alleles (40% and 13 % respectively) (Das *et al.* 1998). This study has shown the broader spectrum of infantile NCL and that infantile NCL is no longer just a Finnish disease.

1.2.5 Mouse models of NCLs

Five well-defined genetic mouse models of the NCLs are available to date. As summarized in Table 1.2, all 5 mouse models reproduce the phenotypes of progressive

neuronal storage disorders that are manifest in the corresponding human NCLs. Three models were generated by gene targeting of *CLN1* (Gupta *et al.* 2001), *CLN2* (Sleat, D.E. and Lobel, P., manuscript submitted), and *CLN3* (Mitchison *et al.* 1999; Wheeler *et al.* 2002) and the other two have been isolated as spontaneous mutations in *CLN6* (Gao *et al.* 2002a) and *CLN8* (Ranta *et al.* 1999).

Table 1.2 NCL mouse models

Disorder	Defective gene	Affected protein	Mouse phenotype	Ref.
Infantile NCL	CLN1/Ppt1	Palmitoyl protein thioesterase-1	Spasticity by age 5 months. Myoclonic jerking and seizures. Fatal by 10 months.	(Gupta et al. 2001; Gupta et al. 2003)
Late Infantile NCL	CLN2/Tpp1	Tripeptidyl peptidase-I	Tremor at 7 weeks and then ataxia, median survival 4.5 months.	a
Juvenile NCL	CLN3	Lysosomal transmembrane protein	Neuropathological abnormalities. Motor coordination deficits at 6 months.	(Mitchison et al. 1999), b
Variant Late-Infantile NCL	CLN6(Nclf)	Putative transmembrane protein	Progressive retinal atrophy. Gait disturbance and weakness in limbs evident by 6 months and severe paralysis by 9 months.	(Bronson et al. 1998; Gao et al. 2002a; Wheeler et al. 2002)
Epilepsy with mental retardation	CLN8(Mnd)	Putative transmembrane protein	Hindlimb weakness and ataxia at 6 to 7 months. Behavioral abnormalities.	(Bronson et al. 1993; Ranta et al. 1999; Bolivar et al. 2002)

^aSleat, D.E. and Lobel, P., unpublished data.

^bWeimer, J. M. and Pearce, D. A., unpublished data.

Overall, the symptoms and the severity caused by the loss of function mutation in each mouse model are closely consistent with its human counterparts. Even though there are still many gaps to fill in our understanding of the pathogenesis of NCLs, these mouse models will serve as important tools to achieve further progress.

1.2.6 Neurodegeneration and the NCLs

In contrast to the classical lysosomal storage disorders (LSDs), biochemical analyses of the storage material in the NCLs did not provide clues as to the underlying defects, due either to the heterogeneous nature of the metabolites (proteins or lipid-modified proteins) or perhaps because the metabolites are toxic. Whereas most other LSDs are characterized by engorgement of affected organs by copious amounts of storage material, the storage in the NCLs is relatively scant and the phenotype is predominantly one of cell loss and neurodegeneration. Because of these unique phenotypes of neuronal loss and neurodegeneration caused by storage material, NCLs were not initially understood to be as lysosomal disorders. However, with the appreciation that most of the underlying genes encode lysosomal enzymes or lysosomal proteins, it is now clear that the NCLs belong to the family of lysosomal storage disease (reviewed in section 1.3).

Interestingly, all NCLs show a common phenotype, neuronal cell death, although individual defects, the age of onset of symptoms and progression of disease are all variable. Three types of mechanism for cell death are known as summarized in Table 1.3; apoptosis (type 1 cell death), autophagy (type 2 cell death) and necrosis (type 3 cell death) (Kerr *et al.* 1972; Schweichel *et al.* 1973; Clarke 1990).

Table 1.3 Summary of three different cell death mechanisms

Type	Characteristics	Ref.
Apoptosis	Cell shrinkage, plasma membrane blebbing, nuclear pyknosis, Chromatin condensation, DNA fragmentation.	(Kerr et al. 1972)
Autophagy	Formation of numerous cytoplasmic autophagic vacuoles Lysosomal degradation	(Schweichel et al. 1973)
Necrosis	Lack of lysosomal involvement Swelling of intracellular organelles Formation of empty space in the cytoplasm	(Clarke 1990)

The mechanisms of apoptotic pathways have been well documented in the last decade through identification of key components including a family of cysteine proteases called caspases, a family of adaptor proteins such as Apaf-1, and a family of mitochondria-associated proteins called Bcl-2. These proteins have been shown to control apoptosis in many different systems, including neurons (Yuan *et al.* 2000). In NCLs, apoptosis is implicated to be a major mechanism of cell death (Mitchison *et al.* 2004). However, the role of autophagy either alone or in conjunction with apoptosis, cannot be excluded. For example, no apoptotic cell death of neurons was observed in CLN3 and CLN6 knockout mice. Instead, autophagic vacuoles were discovered in the electron micrographs in CLN3 knockout mice (Mitchison *et al.* 2004).

Two major compartments for degradation of macromolecules and organelles in eukaryotic cells are the proteasome and the vacuole/lysosome. Under a variety of physiological conditions, most short-lived intracellular molecules are selectively turned over

by the ubiquitin-proteasome pathway (Hochstrasser 1996). The ubiquitin-proteasome utilizes a series of enzymatic actions of E1 (the ubiquitin-activating enzyme), E2 (the ubiquitin conjugating enzyme) and E3 (the ubiquitin-protein ligase) to tag the ubiquitin moiety to the target protein via lysine residues, which are subsequently recognized by the 26S proteasome. The 26S proteasome, which is comprised of the 20S core particle and 19S regulatory particle, degrades the ubiquitin tagged substrates into small peptides by proteases embedded inside the 20S proteolytic core. However, the ubiquitin-proteasome pathway system functions in the degradation of smaller and soluble proteins (cytoplasmic or nuclear), while vacuole/lysosomal system targets the long-lived, larger and more complex substrates such as membrane proteins, protein complexes and organelles (Mortimore *et al.* 1987; Hochstrasser 1996).

Autophagy is a Greek word and means self (“auto”) eating (“phagy”). In biological terms, autophagy is a degradation pathway to the vacuole/lysosome involving the sequestration of cytoplasmic portions and intracellular organelles in a double membrane vesicle called the autophagosome (Klionsky *et al.* 2000). Although the origin of autophagocytic membrane is not yet clear, it has been suggested that the formation of autophagic vacuoles is initiated from the membranes of rough endoplasmic reticulum (RER) (Dunn 1990). Three types of mechanism have been suggested for autophagy: macroautophagy, microautophagy and chaperone-mediated autophagy (Seglen *et al.* 1992; Dunn 1994; Blommaart *et al.* 1997). Chaperone-mediated autophagy and microautophagy have not been characterized in detail. Chaperone-mediated autophagy is suggested as a secondary response to macroautophagy, which occurs temporally (Klionsky *et al.* 2000).

Microautophagy is triggered by invagination of vacuolar membrane to surround organelles such as occurs in the degradation of peroxisomes (Yuan *et al.* 1997; Sakai *et al.* 1998).

Macroautophagy is a conserved and well-controlled process that occurs in all eukaryotic cells. It is an important process controlling the balance between anabolism and catabolism during normal cell growth and development in response to starvation, differentiation, aging and death. At least two steps are involved in macroautophagy. Initial autophagosomes are formed after portions of cytoplasm are sequestered by membranous vesicles. By fusion of autophagosomes with pre-existing vacuole/lysosomes, the resulting autophagosomes will gain proteolytic enzymes and undergo autolysosomal degradation. The molecular mechanism of macroautophagy has been best revealed in yeast reverse genetics using *Saccharomyces cerevisiae*. Genes involved in the formation and regulation of the autophagosome were identified and characterized by genetic screening. At least 16 genes (*APG* and *AUT*) were identified that were required for formation of autophagosomes. For the docking and fusion of autophagosome and lysosome, Class C *VPS* genes are also required (Tsukada *et al.* 1993; Thumm *et al.* 1994; Sato *et al.* 2000; Seals *et al.* 2000; Khalfan *et al.* 2002). Because many of these genes have their homologous counterparts in higher eukaryotic cells, study of autophagy genes in lower organisms has led to a better understanding of the process in mammalian cells.

In mammalian cells, autophagy is induced by amino acid starvation. The autofluorescent drug monodansylcadaverine (MDC) has been used as a specific marker for autophagosomes in CHO cells. Vinblastine, a microtubule depolymerizing agent, also induces the accumulation of autophagic vacuoles by preventing their degradation, which

increases the accumulation of MDC and alters the size and distribution of autophagic vacuoles (Munafo *et al.* 2001). It has been reported that the distribution of Rab24 is altered in CHO cells by induction of autophagy through amino acid deprivation. GFP-tagged Rab24 stained vesicles were labeled with the specific autophagosome marker MDC and colocalized with autophagosome protein LC3 (the mammalian ortholog of the yeast protein Apg8/Aut7), suggesting Rab24 is involved in the autophagic pathway (Munafo *et al.* 2002).

Autophagy is a dynamic process involving remodeling of cytoplasm and organelles by sequestering macromolecules for delivery to vacuole/lysosome so that the cargo is degraded and recycled. The mechanism of autophagy in the mammalian system is still unclear, although extensive studies in yeast have begun to reveal the molecular mechanism of autophagy and vacuole/lysosomal degradation in the past decade. In Chapter 4 of this dissertation, autophagy will be discussed as a possible mechanism of lipid-linked oligosaccharide (LLO) accumulation in NCL mouse models.

1.3 Dolichol Metabolism

1.3.1 Dolichol biosynthesis

As briefly mentioned earlier, dolichol is a long chain polyisoprenoid with 14-21 isoprene units with the chain length varying in different species (Pennock *et al.* 1960; Schenk *et al.* 2001). Dolichol is synthesized by the common isoprenoid pathway with other final products such as cholesterol and ubiquinone (Hemming 1992). These pathways diverge after the synthesis of farnesyl pyrophosphate (FPP) as shown in Figure 1.2, and *cis*-prenyl

transferase is the first enzyme in dolichol biosynthesis after the branching point (Voet et al. 1990).

Figure 1.2 Pathway of isoprenoid metabolism

Then, a series of isopentyl pyrophosphate (IPP) additions produces polyprenyl pyrophosphate. Isoprenoid phosphatase hydrolyzes two phosphate groups, yielding polyprenol. Finally, polyprenol reductase converts the polyprenol to the mature polyisoprenol, dolichol, in the presence of a cofactor, reduced nicotinamide adenine dinucleotide phosphate (NADPH) as shown in Figure 1.3 (Grunler *et al.* 1994). All reactions down to the synthesis of FPP in Figure 1.2 are localized in cytosol where the enzymes and substrates are present, and the resulting cytosolic pool of FPP is then utilized as the substrate for cholesterol and dolichol biosynthesis in the ER and for ubiquinone biosynthesis in mitochondria (Trumpower *et al.* 1974; Wong *et al.* 1982b; Carroll *et al.* 1992; Cohen *et al.* 1992; Stamellos *et al.* 1993). *cis*-Prenyltransferase activity is also detected in peroxisomes, implying dolichol biosynthesis is not restricted to microsomes (Appelkvist *et al.* 1989).

Interestingly, Wong and Lennarz have demonstrated by kinetic studies and subcellular fractionation studies using rat liver that dolichol is transferred to the lysosomal fraction and preferentially accumulated in lysosomes after being synthesized in microsomes (Wong *et al.* 1982a; Wong *et al.* 1982b).

De novo synthesis of the most biologically active form of dolichol, Dol-P, is catalyzed by dolichol kinase at the first carbon of the α -isoprenoid group as shown in Figure 1.3. In *S. cerevisiae*, the *SEC59* gene encodes dolichol kinase (DK). The temperature sensitive mutant, *sec59-1*, in mutant cells has only 48% of DK activity at the permissive temperature and less than 10% of DK activity at the restrictive temperature compared to wild type DK. The Dol-P pool in mutant cells dries up almost instantaneously upon the temperature shift to the restrictive temperature,

Figure 1.3 *De novo* synthesis of dolichol phosphate (Dol-P). Other routes, such as involving reduction of polyprenol-P or dephosphorylation of Dol-P-P, are also possible.

resulting in impairment of asparagine (N)-linked glycosylation (Bernstein *et al.* 1989; Heller *et al.* 1992). cDNA from human brain that encodes the mammalian ortholog of DK was also identified and characterized (Fernandez *et al.* 2002).

Dol-P is also utilized in biosynthesis of serine/threonine (O)-linked mannosylation, and tryptophan (C)-linked mannosylation, as well as glycosylphosphatidylinositol (GPI)-anchored proteins (Imperiali *et al.* 1995). During *N*-linked glycoprotein biosynthesis, Dol-P is the substrate for at least 3 reactions on the cytoplasmic face of the endoplasmic reticulum (ER) membrane: syntheses of GlcNAc-P-P-Dol, mannose-P-dolichol (MPD) and glucose-P-dolichol (GPD) (Gao *et al.* 2002c). As mentioned earlier, the availability of Dol-P is a rate-limiting factor in all of these lipid mediated glycosylations including *N*- and *O*-linked glycoprotein syntheses, and GPI-anchored protein synthesis.

1.3.2 Dol-P in biosynthesis of asparagine (N)-linked glycoproteins

Biosynthesis of N-linked glycoproteins involves a series of enzymatic reactions occurring on the both sides of endoplasmic reticulum (ER) membrane as shown in Figure 1.4. The rate-controlling substrate Dol-P begins the synthesis of the lipid carrier (Dol-P-P-OS) for oligosaccharide transfer to the asparagine residue of nascent polypeptides by accepting GlcNAc-1-P from one of the nucleotide-activated sugar donors (UDP-GlcNAc) (Burda *et al.* 1999). An additional unit of GlcNAc is added to produce a lipid-linked oligosaccharide (LLO) intermediate, GlcNAc₂-P-P-dolichol. Then, five more mannose units are added successively from GDP-Man to yield Man₅GlcNAc₂-P-P-

Figure 1.4 Biosynthesis of lipid linked oligosaccharide (LLO) intermediates in the ER. The mechanism of Dol-P recycling remains uncertain.

dolichol (M_5) on the cytoplasmic face of the ER membrane. The M_5 is then flipped into the luminal side of the ER membrane and four additional mannose units are added to produce $\text{Man}_9\text{GlcNAc}_2\text{-P-P-dolichol}$ (M_9). In *S. cerevisiae*, Rft1p is found to be necessary for this flipping process on the ER membrane (Helenius *et al.* 2002). M_5 must be assembled outside of the ER because GDP- Man cannot be translocated into the ER lumen, requiring a flippase activity on the ER membrane (Burda *et al.* 1999). MPD and GPD, which are the donors of mannose and glucose onto LLO intermediates inside the ER, also have to be translocated into the lumen of the ER. However, proteins mediating translocation of MPD and GPD have not been identified (Burda *et al.* 1999). On the luminal side of the ER, 3 more glucose units are added sequentially onto M_9 , yielding $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-dolichol}$ (G_3M_9). Finally, from the mature LLO, G_3M_9 is transferred by oligosaccharyltransferase (OST) onto the target asparagine residue (Asn-Xxx-Ser/Thr) in the newly synthesized polypeptides in the lumen of the ER, generating *N*-linked glycoproteins (Gao *et al.* 2002c).

Gao and Lehrman have introduced a modern technique of fluorophore-assisted carbohydrate electrophoresis (FACE) to study LLO biosynthesis (Gao *et al.* 2002b; Gao *et al.* 2002c; Gao *et al.* 2003). This FACE system is a relatively simple and exceptionally sensitive method for labeling and detecting LLO intermediates from cells and tissues without using radioisotopes. In Chapter 4 of this dissertation, LLO profiles of five neuronal ceroid lipofuscinosis (NCL) mouse models, 3 lysosomal storage disease (LSD) mouse models and a PPT2 knock-out mouse using FACE analysis will be presented, and LLO accumulation in NCLs will be discussed in detail.

1.3.3 Recycling of dolichol phosphate (Dol-P)

The level of Dol-P, a rate-controlling factor in the biosynthesis of *N*-linked glycoproteins, is proposed to be maintained by *de novo* synthesis from free dolichol by dolichol kinase (DK) (Burda *et al.* 1999). There is another way of maintaining the level of Dol-P by converting from Dol-P-P to Dol-P after the oligosaccharide (Glc₃Man₉GlcNAc₂) transfer onto proteins (Schenk *et al.* 2001). Once the oligosaccharides are transferred onto the proteins, Dol-P-P is released on the luminal surface of the endoplasmic reticulum (ER). In order for Dol-P-P to be re-utilized as a glycosyl carrier lipid for additional rounds of LLO biosynthesis, it must be converted to Dol-P and translocated to the cytoplasmic side of the ER (Schenk *et al.* 2001).

The *S. cerevisiae* *CWH8* locus is believed to encode this dolichol pyrophosphatase activity. *CWH8* null mutant cells are viable but grow much more slowly than wild type cells. They also show inefficient *N*-linked glycosylation on secretory proteins such as carboxy peptidase Y (CPY). They produce normal dolichol and a normal length of dolichol-linked oligosaccharide (LLO) intermediates at a much reduced level (20%) as compared to wild-type yeast (van Berkel *et al.* 1999). Later, it was confirmed that Cwh8p had dolichol pyrophosphate phosphatase activity *in vitro* specifically converting Dol-P-P to Dol-P on the luminal side of the ER (it was therefore renamed as Dolpp1p) (Fernandez *et al.* 2001). Dolpp1p is recovered in crude microsomal fractions, but its subcellular location had not been established. In Chapter 3 of this dissertation, cloning of mouse *DOLPPI* will be presented and further characterization of mouse Dolpp1p including its subcellular localization will be discussed in detail.

1.4 Palmitoyl Protein Thioesterase-1 (PPT1)

1.4.1 Discovery

In 1993, Camp and Hofmann first discovered palmitoyl protein thioesterase-1 (PPT1) from bovine brain as an enzyme that cleaved the palmitate from H-Ras *in vitro* (Camp *et al.* 1993b), and the human PPT1 gene was then mapped to 1p32 to metaphase chromosomes by fluorescent in situ hybridization (FISH) (Schriner *et al.* 1996). Simultaneously, the Peltonen group in Finland assigned the locus 1p32 as a candidate gene site for an autosomal recessive disorder called infantile neuronal ceroid lipofuscinosis (INCL) by positional cloning (Jarvela 1991; Vesa *et al.* 1995). Eventually, the two groups agreed that they were studying ultimately the same gene by confirming multiple mutations in PPT1 gene in INCL patients and by showing no residual PPT activity from brain tissues and lymphoblasts derived from the patients (Vesa *et al.* 1995).

1.4.2 PPT1, a thioesterase

The substrate H-Ras was used in the enzyme assay for PPT1 during the purification from bovine brain tissues, because H-Ras is palmitoylated via S-acylation at the two C-terminal cysteine residues (Cys₁₈₁ and Cys₁₈₄) (Kato *et al.* 1992). S-acylation is a post-translational modification of proteins that utilizes a thioester bond between the carboxyl end of the fatty acid and the sulfhydryl group of the cysteine residue (Casey 1995). In addition to palmitoylation, H-Ras also has a site for carboxy methylation and farnesylation (Cys₁₈₆) at the C-terminus (Kato *et al.* 1992). For farnesylation, a thioether linkage to the cysteine residue is used instead of thioester linkage. Therefore, it has been demonstrated that PPT1

specifically cleaves off palmitate groups from H-Ras leaving farnesyl group intact (Camp *et al.* 1993b).

In mammals, the PPT1 cDNA encodes 306 amino acids and contains an N-terminal leader sequence (first 25 amino acids). PPT1 is a classical globular monomeric enzyme, which possesses an α/β hydrolase fold typical of lipases and a classical catalytic triad consisting of serine, aspartic acid and histidine residues (Camp *et al.* 1993b; Bellizzi *et al.* 2000). PPT1 also has three potential sites for asparagine (N)-linked glycosylation (Asn₁₉₇, Asn₂₁₂ and Asn₂₃₂). Mutations of those glycosylation sites cause a reduction of enzyme activity and mutations of all three sites inactivate PPT1 completely *in vitro* due to effects on protein folding and stability (Bellizzi *et al.* 2000). An *in vivo* substrate for PPT1 has not been identified but in addition to palmitoylated proteins, PPT1 hydrolyzes long chain fatty acyl CoAs with fatty acid chain length of 14 to 18 carbons *in vitro* (Camp *et al.* 1994). The crystal structure for PPT1 has shown that PPT1 cannot bind lipid chains less than 10 carbons because they are not long enough to make contact with the critical residues of PPT1 (Calero *et al.* 2003). This observation has explained why PPT1 had almost no activity with acyl CoA substrates of six carbons or less (Camp *et al.* 1993b).

1.4.3 PPT1, a lysosomal enzyme

PPT1 has been demonstrated to be a lysosomal enzyme by Verkruyse and Hofmann, although recombinant PPT1 showed a broad neutral pH optimum (Verkruyse *et al.* 1996). The experiments showed that recombinant PPT1 was taken up by COS cells via the mannose 6-phosphate receptor pathway, a hallmark of lysosomal enzyme trafficking. PPT1 activity

also fractionated with lysosomal markers by Percoll density gradient analysis, strongly suggesting its lysosomal localization (Verkruyse *et al.* 1996). Lysosomal localization of PPT1 was also confirmed by immunofluorescence studies (Hellsten *et al.* 1996).

Defective PPT1 initiates an accumulation of [³⁵S]cysteine-labeled lipid thioesters in lymphoblasts derived from INCL patients (Lu *et al.* 1996). The accumulation of lipid thioesters is time dependent and requires prior protein synthesis, indicating that the cysteine containing lipid thioesters probably originated from fatty acylated proteins. The accumulation is corrected by incubating the cells with recombinant PPT1, which was taken up via the mannose 6-phosphate receptor mediated pathway (Lu *et al.* 1996). It also has been shown that the accumulated radiolabeled lipid thioesters cosedimented with lysosomal markers, confirming that the accumulated lipid esters were PPT1 substrates *in vivo* (Lu *et al.* 2002).

1.4.4 PPT1 knock-out mouse

Using a gene targeting strategy, a PPT1 null mutant mouse was engineered and its phenotypes were well characterized and documented (Gupta *et al.* 2001; Bible *et al.* 2004). PPT1 knock-out mice are viable and fertile. However, the mice show severe cortical atrophy, spontaneous seizures and premature death by 10 months. PPT1 knock-out mice exhibit a lack of grooming, frequent myclonic jerks and seizures from 3-4 mo of age. PPT1 deficiency also affects motor functions such as a progressive gait abnormality and spasticity (a “clasping” phenotype) beginning at 5 months of age which progresses to hind-limb paralysis (Gupta *et al.* 2001).

Autofluorescent storage material accumulation is evident in brain tissues from all PPT1 knock-out mice examined (the earliest age of mice examined were 4 wk-old). Neuronal GROD (granular osmophilic deposits), a hallmark of INCL, are also identified in PPT1 knock-out brain and they are indistinguishable from GROD seen in human patients (Das *et al.* 1998; Gupta *et al.* 2001). In PPT1 knock-out brain, a 46% reduction of volume in thalamus as well as a 35% and a 30 % reduction in the cortex and striatum are observed, respectively. Cortical thinning probably due to neuronal loss is also observed in different regions of the PPT1 knock-out brain (Bible *et al.* 2004). Terminal dUTP nick end-labeling (TUNEL) assay shows apoptotic neurons in the Purkinje layer of the cerebellum in PPT1 knock-out brain, implying apoptosis as a cell death mechanism in PPT1 knock-out mouse brain (Gupta *et al.* 2001).

1.4.5 *PPT1* ortholog in *Schizosaccharomyces pombe*

cDNAs for *PPT1* have been cloned and characterized from human, bovine, rat, mouse, fruit fly and fission yeast (Camp *et al.* 1994; Schrinier *et al.* 1996; Salonen *et al.* 1998; Glaser *et al.* 2003; Cho *et al.* 2004). The 25 amino acid-long N-terminus leader sequences are less obvious in *PPT* orthologs in *Drosophila* and *S. pombe* but the classical “catalytic triad” residues of Ser-Asp-His in the active site of typical thioesterases are very well conserved in all the species from human to fission yeast (Glaser *et al.* 2003; Cho *et al.* 2004). The *Drosophila* ortholog of *PPT1* is 55% identical and 72% similar to human *PPT1*, and flies with a homozygous deletion of *PPT1* show almost complete abolition of PPT1 activity using the fluorometric substrate 4-methylumbelliferyl-6-thiopalmityl- β -D-

glucoside, but no apparent phenotype was observed (Glaser *et al.* 2003). Overexpression of a *PPT1* ortholog in *Drosophila*, however, was reported to cause apoptotic cell death in the visual system, suggesting that tight regulation of PPT1 might be important in neuronal cell survival (Korey *et al.* 2003).

S. pombe is a single-celled free living archiascomycete fungus sharing many features associated with more complex eukaryotic cells. Because the genome of *S. pombe* can be manipulated experimentally, it has served as an excellent model organism for many studies, particularly those involving cell-cycle control, mitosis and meiosis (Davis *et al.* 2001), and DNA repair and recombination (Humphrey 2000). *S. pombe* is also increasingly used for investigating the functions of human disease genes. About 50 genes (out of a total complement of approximately 4,800) are orthologous to known human disease genes, including those underlying various metabolic, cardiac, renal, and neurological diseases, and cancer. Most of these genes are also found in *Saccharomyces cerevisiae* (another common fungal model). However, two known disease-associated genes (SPAC630.13c and SPBC530.12c) are found only in *S. pombe*, and not in *S. cerevisiae* (Wood *et al.* 2002). One of the genes, SPBC530.12c, encodes the *S. pombe* ortholog of the human *PPT1* gene. (The other encodes a gene associated with tuberous sclerosis (*TSC2*)).

Interestingly, examination of SPBC530.12c reveals that it is a fusion gene consisting of the *S. pombe PPT1* ortholog followed by a single in-frame open reading frame (ORF), which is an ortholog of *DOLPPI*, a gene encoding dolichol pyrophosphate phosphatase-1 (Dolpp1p), an enzyme also implicated in dolichol metabolism as reviewed earlier. In Chapter

2 of this dissertation, the cloning and characterization of this *S. pombe* ortholog gene (SPBC530.12c) will be presented in detail.

CHAPTER TWO

PPT1 ortholog in *Schizosaccharomyces pombe*

2.1 Introduction

As described in the introduction, *S. pombe* is fission yeast, a single-celled free living archiascomycete fungus sharing many features associated with more complex eukaryotic cells. Because the genome of *S. pombe* can be manipulated experimentally, it has served as an excellent model organism for many studies. Bioinformatics screening using amino acid sequence of human *PPT1* has resulted in identification of an uncharacterized gene (SPBC530.12c) as the *PPT1* ortholog in the *S. pombe* genome. Interestingly, examination of SPBC530.12c reveals that it is a fusion gene consisting of the *S. pombe PPT1* ortholog followed in the same open reading frame (ORF) by sequence encoding an ortholog of *DOLPPI*, a dolichol pyrophosphate (Dol-P-P) phosphatase-1 (Dolpp1p), an enzyme implicated in dolichol metabolism. Dolpp1p is a transmembrane protein that catalyzes the conversion of Dol-P-P to Dol-P, and is postulated to play a role in the recycling of dolichol utilized in the synthesis of the dolichol pyrophosphate oligosaccharides (Dol-P-P-OS) in the ER.

Dol-P-P-OS are intermediates in the asparagine (N)-linked glycosylation of proteins (Rush et al. 2002). Dolpp1p null mutant alleles in *S. cerevisiae* produce normal dolichol and dolichol-linked oligosaccharide intermediates at a reduced level (20%) as compared to wild-type yeast. The presence of a putative fusion protein containing both *PPT1* and *DOLPPI*

orthologs in *S. pombe* suggests coordinate regulation of the synthesis of the two polypeptides in *S. pombe*.

In this chapter, I have ablated the SPBC530.12c gene (hereafter referred to as *pdf1*, *ppt1-dolpp1 fusion 1*) and determined the consequences of inactivating mutations in the Ppt1p and Dolpp1p domains through plasmid complementation assays. I have also produced a polyclonal antibody against the C-terminus of Pdf1p to examine possible post-translational processing.

2.2 Experimental Procedures

2.2.1 Yeast strains, media and genetic methods

Genotypes of *S. pombe* strains used in this study are listed in Table 2.1. All strains were maintained on yeast extract plus supplement (YES) agar plates or under selection on

Table 2.1 *S. pombe* strains used in this study and their genotypes

Edinburgh minimal media (EMM) with appropriate supplements as described (Moreno et al. 1991). Yeast cells were transformed using lithium acetate (Alfa et al. 1993). Standard molecular biological techniques were employed (Sambrook et al. 1989).

2.2.2 Identification and subcloning of *pdf1*⁺

The SPBC530.12c gene of *S. pombe* was identified as containing sequences corresponding to a potential human PPT1 ortholog through a BLAST search of GenBankTM using the human PPT1 amino acid sequence (NP_000301) as the query. *S. pombe* cosmid 530 (GenBankTM accession number: AL023634), which contains the SPBC530.12c gene, was obtained from the Sanger Center (<http://www.sanger.ac.uk>). Polymerase chain reaction (PCR) was carried out using pfu polymerase (Stratagene) and cosmid 530 DNA as a template DNA with primers 5'-TAAGAAATTCGACTCAAGACAACAATCACT-3' and 5'-CTTGGATCCCCTTGGGTAATTTTCTGAAC-3'. The amplified product was digested with *EcoRI* and *BamHI* (underlined in the forward and reverse primers, respectively) and subcloned into the plasmid vector pGEM-T-Easy (Promega) to create pGPD1. The entire open reading frame (ORF) was sequenced on both strands and corresponds exactly to nucleotides 37983 through 39794 of AL023634.

2.2.3 Construction of the *pdf1* disruption

Disruption of *pdf1* was performed by removal of a large portion of the open reading frame (Figure 2.1, corresponding to amino acids 69 through 565) of pGPD1 and insertion of a *his3*⁺ gene. Briefly, pGPD1 was digested with *BbsI* and *BlpI* to remove most of the open reading frame and the remaining 3.5 kb fragment (containing vector and flanking sequence)

was rendered blunt-ended. The *his3⁺* gene from pJB1 (a gift from Dr. Luis Rokeach, University of Montréal) (Burke et al. 1994) was amplified using pfu polymerase and primers 5'-CAACGTTTTCTTTACTATTGCAC-3' and 5'-ACGCGTGAATGGACTGTTGGCTG-3' and ligated into pGEM-T-Easy (Promega). A 2.1 kb *NotI* fragment containing the *his3⁺* gene was rendered blunt-ended and ligated to the 3.5 kb fragment of pGPD. The resultant plasmid (pGPDH1) was digested with *NotI* and the 2.6 kb insert was transformed into a wild-type diploid strain SC2478. *His⁺* diploids were selected and designated as SC41. Replacement of the wild-type allele by the disrupted gene was confirmed by Southern analysis using a randomly primed labeled probe generated by PCR amplification of a 300 bp portion of pGPD using primers 5'-CCCTTGGGTAAATTTCTGAAC-3' and GTCTTCAAATTCGTTGTCACC-3'. The correct targeting of the deletion cassette into the genomic locus was also verified by PCR. Primers were designed that were specific to the upstream, downstream and internal regions of the ORF, and to the internal region of the *his3⁺* cassette. To determine the effect of the gene disruption on spore viability, SC41 cells were plated on malt extract (ME) plates to induce sporulation. After 36 to 48 hours, the presence of asci was confirmed under the light microscope and tetrad dissection was performed using a micromanipulator as described previously (Alfa et al. 1993).

2.2.4 Expression Plasmids

The ORF of *pdf1⁺* was amplified by PCR using pGPD1 as a template and the amplified product was subcloned into three plasmid vectors; pREP1, pAAU (a gift from Steven Marcus, MD Anderson Cancer Center) and pAAL. The pAAL vector was created by

replacing the *ura4⁺* marker with *LEU2⁺* in pAAU by digestion with *Hind*III and ligation. Point mutations were introduced in the *pdf1⁺* ORF using the QuickChange Site-Directed Mutagenesis Kit (Stratagene). Oligonucleotide sequences used in the construction of point mutations are available upon request. The truncation mutation (Δ 373-602) was constructed by PCR using pGPD1 as template.

2.2.5 Isolation of haploid *pdf1* Δ strains complemented by *pdf1⁺*

SC41 cells were transformed with pAAU-*pdf1⁺*, and *his⁺* and *ura⁺* transformants were selected on medium lacking adenine, histidine and uracil. Transformants were induced to sporulate on ME plates, the ascus walls were digested with glusulase (Sigma), and the individual spores were germinated on plates lacking histidine and uracil. The resulting colonies were examined as *his⁺*, *ade⁻* haploids only if they were also *ura⁺*, indicating plasmid rescue of the disruption phenotype. Loss of the wild-type allele was confirmed by Southern analysis. The haploid strains were designated SC41R, SC41U or SC41L, for strains complemented by pREP1-*pdf1⁺*, pAAU-*pdf1⁺* and pAAL-*pdf1⁺*, respectively.

2.2.6 Structure-function analysis of *pdf1⁺* by plasmid shuffling

SC41U cells were transformed with wild type pAAL-*pdf1⁺* or with plasmids containing mutations as indicated in the Figure Legends. Transformants were selected on a medium lacking leucine and uracil. Each transformant was then streaked onto medium containing 0.1% 5-fluoroorotic acid (5'FOA) and 50 μ g/ml uracil (Liang et al. 2001) and was grown at 30°C for 4 days to promote the loss of the *ura4⁺* plasmid. The growth of cells in the

presence of 5'FOA was scored to assess the ability of the wild type or mutated pAAL- *pdf1*⁺ to promote viability of the haploid *pdf1*Δ strain.

2.2.7 Vanadate and extracellular pH sensitivity

Sodium orthovanadate (Sigma) was added to medium from a filter-sterilized stock solution (100 mM) after autoclaving. For pH sensitivity experiments, 50 mM MOPS and 50 mM MES was included in the medium and the pH was adjusted by dropwise addition of 10 N NaOH.

2.2.8 Affinity-purified polyclonal antibodies

Three New Zealand White rabbits were each immunized with 300 μg of a synthetic peptide corresponding to amino acid residues 583 to 603 of Pdf1p that was coupled to keyhole limpet hemocyanin using methods described previously (Rush et al. 2002). The antigen was injected intradermally in Freund's complete adjuvant, and rabbits were boosted three times at 3-week intervals with 300 μg of peptide in Freund's incomplete adjuvant. An IgG fraction was prepared from preimmune and immune serum by specific binding to Protein A-Sepharose CL-4B (Pharmacia). The IgG was affinity-purified by specific binding to a column consisting of the peptide cross-linked to SulfoLink coupling gel (Pierce).

2.2.9 Protein extraction and immunoblotting

Cells were grown to mid-log phase in EMM with appropriate amino acids. The harvested cells were washed twice with distilled water and cell lysates were prepared by glass bead lysis in homogenization buffer (20 mM HEPES, pH 7.0, 50 mM potassium

acetate, 5 mM magnesium acetate, 100 mM sorbitol) with the addition of 1 mM dithiothreitol (DTT) and a cocktail of protease inhibitors (2 µg/ml each of leupeptin, pepstatin and aprotinin and 1 mM phenylmethylsulfonyl fluoride) (Liang et al. 2001). Lysates were cleared by centrifugation at 500 x g for 1 min at 4 °C, and resulting supernatants were centrifuged at 20,000 x g for 30 min at 4 °C in a Beckman Optima TLX ultracentrifuge. The supernatant fraction was reserved and the membrane pellet was washed once with homogenization buffer and resuspended in 8 M urea for immunoblotting. Samples were analyzed by electrophoresis in 12.5% SDS-PAGE gels and immunoblotting essentially as described (Rush et al. 2002). Filters were blocked for 1 h with Sea Block (East Coast Biologics) and washed in PBS-T (0.25% (v/v) Tween 20 in phosphate-buffered saline) followed by incubation for 1 h with rabbit anti-peptide polyclonal antibody (0.1 µg/ml). The filters were washed with PBS-T and incubated for 45 min in a solution containing horseradish peroxidase-conjugated secondary antibody (sheep anti-rabbit IgG, Amersham) diluted 1:2500 in PBS-T. The filters were washed and developed using ECL chemiluminescence reagents (Amersham).

2.3 Results

2.3.1 Cloning of the fission yeast *pdf1* gene

A BLAST search of the *S. pombe* genome database using the human PPT1 amino acid sequence yielded a gene (SPBC530.12c) that encodes a 603-amino acid residue protein that contains a Ppt1p domain (31% identical to human Ppt1p), a linker region, and a domain that shares 33% sequence identity to mouse Dolpp1p (Figure 2.1). Figure 2.1 Amino acid sequence alignment (A) and domain structure (B) of proteins encoded by *S. pombe* pdf1, human PPT1, and mouse DOLPP1. Gaps in the sequences are indicated by dashes. Identical amino acid residues are shaded dark gray; similar residues are light gray. The linker region contains two distinct clusters (*) of basic amino acids, which are putative cleavage sites of serine endopeptidase Krp1. Amino acids that participate in catalysis and that were mutated to catalytically inactive residues for the purposes of this study are indicated (*). An acidic linker region of 76 amino acids between the Ppt1p and Dolpp1p domains is indicated by a shaded bar.

and mouse Dolpp1p known to participate in catalysis (i.e., catalytic triad residues Ser115, Asp233 and His289 of human PPT1) (Bellizzi et al. 2000) and the consensus lipid-phosphate phosphatase motif of mouse Dolpp1p (Lys455, His478 and His530) (Rush et al. 2002) are conserved in Pdf1p (Figure 2.1A). The linker region (Figure 2.1B) contains sequences that conform to cleavage recognition sites for a kex-related processing protease, Krp1 (Powner et al. 1998).

2.3.2 Disruption of fission yeast *pdf1* is lethal

To investigate the function of *pdf1*, I constructed and examined the phenotypes of *S. pombe* strains in which *pdf1* was deleted. The *pdf1* gene is 1812 base pairs in length and contains no predicted intron sequences (Figure 2.2A). One copy of the *pdf1* open reading frame (comprising amino acids 69 to 565) was replaced with the *his3*⁺ selectable marker in a diploid *S. pombe* strain and chromosomal deletion of the gene was confirmed by Southern analysis (Figure 2.2B), which yields a 2.2 kb band in wild type (lane 1), 2.2 and 1.8 kb bands in heterozygous diploids (lane 2), and a single band of 5.5 kb in the disruption strain rescued by a plasmid (pREP1-*pdf1*⁺) in the haploid state (lane 3). Correct targeting of the deletion cassette into the genomic locus was also confirmed by PCR as described in Experimental Procedures. Sporulation and tetrad analysis of independently derived heterozygous diploid strains ($\Delta pdf1:: his3^+/pdf1^+$) resulted in only two viable spores, showing a 2:0 segregation (Figure 2.2C). All of the viable spores were *his*⁻ and *pdf1*⁺, indicating that *pdf1* is an essential gene in *S. pombe*.

Figure 2.2 Disruption of *pdf1*⁺. (A) Restriction map and schematic of the *pdf1*⁺ locus. The direction and location of the *pdf1*⁺ ORF are indicated. The position of the probe used for Southern blot analysis is indicated as a shaded box. The location of the *his3*⁺ gene in the *pdf1*Δ::*his3*⁺ disruption construct is shown. An additional *Hind*III site is located within the

his3⁺ gene. (B) Southern blot analysis of the chromosomal *pdf1⁺* deletion. Genomic DNA was digested with *HindIII*, resolved on a 1% agarose gel, and probed with the 0.3-kb fragment indicated in panel A. Lane 1, homozygous wild type *pdf1⁺/pdf1⁺*; lane 2, heterozygous *pdf1 Δ /pdf1⁺* strain; lane 3, homozygous *pdf1 Δ /pdf1 Δ* strain rescued with a plasmid bearing *pdf1⁺*. (C) Tetrad analysis of the *pdf1⁺* gene disruption. A 2:0 segregation ratio resulted from microdissection of heterozygous diploid (*pdf1 Δ ::his3⁺/pdf1⁺*) cells after sporulation. The spores that formed colonies in any tetrad were *his⁻* and hence *pdf1⁺*.

2.3.3 The Dolpp1p domain of Pdf1p is essential for viability whereas the Ppt1p domain is dispensable

To gain a further insight into the role of two domains of the *pdf1*, I analyzed a *pdf1 Δ* strain complemented by various plasmids as shown in Figure 2.3. Of note, the analysis was complicated by an inability to express the *S. pombe* Dolpp1p domain alone in the absence of upstream sequences, presumably due to the need for a signal sequence or other sequences needed for proper Dolpp1p membrane insertion and folding.

A structure-function analysis was performed using a plasmid shuffling technique. First, I isolated a haploid strain SC41U which contains the *pdf1* deletion and harbors the wild type *pdf1⁺* gene within a complementing plasmid (pAAU). Because *pdf1* is an essential gene, only haploid cells containing the plasmid were viable. The SC41U cells were transformed with a second plasmid (pAAL) containing a series of mutant constructs, or *S. cerevisiae* *DOLPP1* or human *PPT1* cDNAs. Those plasmids included specific point mutants, deletion and nonsense mutants within the *pdf1* coding sequences on the plasmid. The growth of each transformant in the presence and absence of 5'FOA was scored (Figure 2.3). As a result, I observed that plasmids bearing inactivating mutations in the Ppt1p domain (Hofmann et al. 2002) (S106A and D226A) that contained an intact Dolpp1p domain complemented the

Figure 2.3 Plasmid shuffling by counterselection on 5-FOA reveals that the Dolpp1p domain is essential for viability. The ability to grow in the presence of 5-FOA indicates complementation of *pdf1Δ* by the indicated plasmid in SC41U haploid cells. The schematic (1 to 8) indicates the amino acid sequences encoded by the complementing plasmid with inactivating point mutations, deletions, or nonsense mutations as indicated: 1, wild-type Pdf1p; 2, Pdf1p Δ 373 to 602; 3, Pdf1p (S106A); 4, Pdf1p (D226A); 5, Pdf1p (K302Stop); 6, Pdf1p (H478A); 7, human Ppt1p; 8, *S. cerevisiae* Dolpp1p. The transformants were streaked to EMM plates supplemented only with adenine (–5'FOA) or adenine, uracil, and 5-FOA (+5'FOA). The growth of each transformant on the plates was scored. +, growth; –, no growth.

lethal phenotype (Figure 2.3, sectors 3 and 4), whereas plasmids truncated before the Dolpp1p domain or bearing a mutation in a highly conserved residue in the phosphate binding pocket of Dolpp1p (Studdert et al. 1991) (H478A) did not rescue the phenotype (Figure 2.3, sectors 2, 5 and 6). Therefore, it is clear that loss of the Dolpp1p domain is

responsible for the lethal phenotype. Interestingly, neither human Ppt1p nor *S. cerevisiae* Dolpp1p expression plasmids alone complemented the lethal phenotype.

2.3.4 Phenotype of Ppt1p-deficient mutants

I observed that while *pdf1*Δ mutants rescued by functional Dolpp1p alone were viable, the growth rate of these cells was somewhat slower than that of the haploid cells containing the wild type *pdf1*⁺ gene (Figure 2.4, left panel). This growth retardation phenotype was reversed by a second plasmid encoding a wild type Ppt1p domain (Figure 2.4, right panel) and an inactivated Dolpp1p domain, suggesting that the growth retardation was caused by the lack of Ppt1p function. Therefore, I have further examined the phenotype of these strains. (Of note, Ppt1p enzymatic activity in these strains could not be measured due to interfering activities or substances in the yeast that raised background signals in the assay).

Figure 2.4 Growth retardation of cells harboring point mutants in the Ppt1p domain. (Left panel) *pdf1*Δ::*his3*⁺ haploids were rescued by plasmids containing wild-type *pdf1*⁺ or plasmids bearing mutations in active site residues of the Ppt1p domain (S106A and D226A). (Middle panel) Rescue of growth retardation by a second plasmid containing a wild-type Ppt1p domain and catalytically inactive Dolpp1p domain. Serial 10-fold dilutions were spotted onto plates containing the relevant amino acid supplement.

2.3.5 Ppt1p-deficient mutants are abnormally sensitive to vanadate and elevated extracellular pH

As Ppt1p is a lysosomal enzyme in mammalian cells and as the fungal vacuole is the equivalent organelle of mammalian lysosome, I thought that it would be of interest to see whether deficiency of Ppt1p function would lead to phenotypes normally associated with vacuolar mutants in fungi, such as sensitivity to sodium orthovanadate or external pH (Banta et al. 1988; Kitamoto et al. 1988; Klionsky et al. 1990; Takeshige et al. 1992; Iwaki et al. 2003). As shown in Figure 2.5A, cells harboring a wild type *pdf1* gene were not affected by vanadate, while cells harboring inactivating mutations in Ppt1p are sensitive to vanadate in a concentration dependent manner (sectors 2 and 3). This sensitivity was reversed when the cells were transformed with a second plasmid containing the wild type Ppt1p domain and an inactive Dolpp1p domain (Figure 2.5A, center column). Inactivating mutations in the Ppt1p domain were also associated with an abnormal sensitivity to elevated extracellular pH, as shown in Figure 2.5B. At pH 5.5, cells complemented with either wild type or plasmids bearing mutations in the Ppt1p domain grow normally. However, when the external pH was elevated above pH 6.0, the haploid cells lacking functional Ppt1p did not grow. This pH sensitivity was reversed when the cells were transformed with a second plasmid containing a wild type Ppt1p domain and an inactive Dolpp1p domain (Figure 2.5B, center column).

Transformation of cells with an empty plasmid vector had no effect on the phenotype (Figure 2.5A and B, third column). These results strongly suggest that Ppt1p activity is required for normal vacuolar function in *S. pombe*.

Figure 2.5 Sensitivity of PPT-deficient cells to sodium orthovanadate and to extracellular pH. (A) Normally inviable *pdf1 Δ ::his3⁺* haploids rescued by wild-type pAAL-pdf1⁺ (1), mutated pAAL-pdf1(S106A) (2), or pAAL-pdf1(D226A) plasmids with mutations in the Ppt1p domain (3) were exposed to various concentrations of sodium orthovanadate for 4 days at 30°C. Mutations in the Ppt1p domain conferred sensitivity to sodium orthovanadate in a concentration-dependent manner. The sensitivity was reversed when the cells were transformed with a second plasmid, pAAU-pdf1(H478A), containing wild-type PPT and an inactivating mutation in the Dolpp1p domain (sectors 4 to 6). Empty vector controls are shown in sectors 7 to 9. (B) Yeast cells were incubated at 30°C for 4 days on EMM adjusted to the indicated pH. Ppt1p-inactivating mutations conferred an abnormal sensitivity to high pH to the cells. The sensitivity to higher pH was reversed when the cells were transformed with a second plasmid containing a wild-type PPT domain and an inactivating point mutation in the Dolpp1p domain (sectors 4 to 6). This suggests that the pH sensitivity is due solely to the absence of wild-type Ppt1p activity in the cells. Note that even normal *S. pombe* cells were unable to grow at pH 7.0. Empty vector controls are shown in sectors 7 to 9. (C) The human PPT1 gene activity was able to complement the phenotypes of PPT-deficient mutants. A second plasmid containing a human PPT1 cDNA (pAAU-hPPT1) was transformed into the cells. Transformants were streaked onto plates containing either 4 mM sodium orthovanadate or medium buffered to pH 6.5.

I also tested for a number of other phenotypes, especially those associated with defects in cell wall integrity, as is seen in Dolpp1p (CWH8) mutants in *S. cerevisiae* (van Berkel et al. 1999; Fernandez et al. 2001). Ppt1p deficient growth was unaffected in the presence of calcofluor white (up to 1 mg/ml), sorbitol or glucose (2 M), potassium chloride (0.9 M) or glycerol (as a sole carbon source). In addition, staining with the dye FM4-64, which reveals defects in endocytosis in *S. pombe vps* mutants (Takegawa et al. 1995), was unaffected, when observed after 30 minutes of incubation and up to 16 hours after incubation. Addition of vanadate (4 mM) or upward adjustment of extracellular pH to 6.5 for 3 h prior to staining had no effect. Evaluation of wild-type and Ppt1p deficient cells by electron microscopy revealed no significant differences in vacuolar morphology, and no clear accumulations of granular osmiophilic deposits were noted. In addition, heat sensitivity (as

assessed by growth at 37°C) and cold sensitivity (growth at 23°C) were indistinguishable from wild-type.

2.3.6 Functional equivalence of human and *S. pombe* Ppt1p domains

The presence of vacuolar phenotypes in the cells lacking Ppt1p function allowed testing of whether the human PPT1 ortholog would substitute for the *S. pombe* gene to complement these phenotypes. As shown in Figure 2.5C, a human PPT1 cDNA reestablished *S. pombe* cell viability in the presence of vanadate and at elevated extracellular pH. These results indicate that *S. pombe* can be used as a model organism for the study of Batten disease.

2.3.7 Posttranslational processing of Pdf1p.

In order to determine whether the two functional domains of Pdf1p remain associated as a single polypeptide or whether they are subject to post-translational proteolytic processing, I made an antibody that recognizes the carboxyl terminus of Pdf1p, and used it to examine the molecular masses of proteins produced from plasmid-derived expression of Pdf1p (Figure 2.6). Membrane fractions were prepared from the yeast and solubilized samples were subjected to SDS-PAGE and transferred onto nitrocellulose membranes for immunoblotting. In Figure 2.6A, lane 1 (wild type), one major band at 31 kDa and two minor bands at 101 kDa and 33 kDa are seen. The major band corresponds precisely to the predicted molecular mass of the Dolpp1p domain (in the absence of the linker region), whereas the upper minor band at 101 kDa corresponds to the full-length unprocessed Pdf1p. The Pdf1p linker region contains two putative cleavage sites for the kex-related

A**B****C**

Pdf1p SLFPEKR³⁴⁴ NFKELTMRKR³⁵⁴
 Krp1p SSIRKR⁸² GIDAGILELERQTRPRWRYKR¹⁰²

Figure 2.6 Posttranslational processing of Pdf1p at dibasic cleavage sites. (A) Membrane fractions of cell lysates were prepared, separated by SDS-PAGE, and transferred to

nitrocellulose for immunoblotting with an antibody that recognizes the carboxyl terminus of Pdf1p. Cells were expressing either wild-type Pdf1p or Pdf1p that contained point mutations in the linker domain (R344A, R354A, or both mutations). Substitution of alanine for arginine at position 354 blocks the proteolytic cleavage, suggesting that arginine 354 is crucial for the posttranslational processing. (B) Schematic of Pdf1p cleavage sites. Two clusters of dibasic motifs, KR³⁴⁴ and RKR³⁵⁴, are indicated. (C) Comparison of known cleavage sites for Krp1p within Krp1p itself (autocatalytic sites) versus putative Krp1p cleavage sites within the Pdf1p linker region. Note that the order of internal and primary sites for Krp1p (Davey *et al.* 1994; Powner *et al.* 1998) along the polypeptide is reversed and the number of intervening amino acids between the two sites is smaller in Pdf1 (10 versus 20). In addition, the arginine in the primary site of Krp1 is replaced by leucine in Ppt1p.

endopeptidase designated Krp1p (Davey *et al.* 1994; Powner *et al.* 1998). Mutation at one of the two putative Krp1p cleavage sites (R344A) did not prevent cleavage of the linker domain (Figure 2.6A, lane 2) but did increase the ratio of the unprocessed to the processed form. However, mutation of the dibasic motif at the internal site (R354A) (Figure 2.6B, C) essentially abolished cleavage (Figure 2.6A, lane 3). Mutation of the dibasic motifs at both the primary and internal sites also prevented the processing of Pdf1p and increased the level of precursor Pdf1p (Figure 2.6A, lane 4). These results suggest that Pdf1p is proteolytically cleaved to form distinct Ppt1p and Dolpp1p domains and that Arg354 is crucial for the posttranslational processing.

2.4 Discussion

In the present study, I demonstrated that an ortholog of human PPT1 is present in the genome of *S. pombe* as a fusion gene with a partner, *DOLPPI*. The entire open reading frame of the *pdf1* gene is translated as a unit and subjected to post-translational proteolytic processing. Mutation at either one of two consensus sequences for the endopeptidase Krp1p inhibits processing whereas mutation at both sites abolishes it. I found that Dolpp1p function

is absolutely essential for viability in *S. pombe*. However, lack of Ppt1p function causes hypersensitivity to elevated extracellular pH and to sodium orthovanadate. The human *PPT1* cDNA complements these phenotypes, suggesting that the function of *PPT1* has been conserved throughout evolution.

Abnormalities in lysosomal pH homeostasis in the juvenile-onset form of Batten disease were first uncovered through the study of a yeast model of the disease (Pearce et al. 1997; Pearce et al. 1998; Pearce et al. 1999a; Pearce et al. 1999b; Pearce 2000). Juvenile onset Batten disease is caused by mutations in *CLN3*, which encodes a multi-membrane spanning intrinsic lysosomal membrane protein of unknown function (Lerner et al. 1995). The orthologous *S. cerevisiae* gene, *BTNI*, is an intrinsic vacuolar protein. In contrast to Ppt1p-deficient *S. pombe*, *BTNI* Δ cells do not exhibit an overt phenotype referable to defective vacuolar function (in over 100 experimental conditions screened (Pearce et al. 1999a)), with the exception that the cells are resistant to a primary amine growth inhibitor, D-(-)-threo-2-amino-1[p-nitrophenyl]-1, 3-propanediol (ANP). The ANP resistance of *BTNI* Δ cells was shown to be related to a subtly enhanced acidification of the external medium, and *BTNI* Δ strains have a slightly more acidic vacuolar pH in early phases of growth (Pearce et al. 1999a). The human *CLN3* cDNA complements this phenotype and substitutes functionally for *BTNI* (Pearce et al. 1998; Pearce et al. 1999b; Chattopadhyay et al. 2000). Observations of more robust phenotypes in Ppt1p vs. Cln3p deficiency appears to hold in yeast, mice (Katz et al. 1999; Mitchison et al. 1999; Gupta et al. 2001) and humans (Goebel 1995).

The phenotypes I observed in Ppt1p loss of function mutations in *S. pombe* (hypersensitivity to elevated extracellular pH and vanadate), while not seen in the yeast model of late-onset Batten disease, do overlap some of those previously described in the *vma* (vacuolar membrane ATPase) and class C and D *vps* (vacuolar protein sorting) mutants of *S. cerevisiae* and *vps33* mutants of *S. pombe* (Bankaitis et al. 1986; Robinson et al. 1988; Nelson et al. 1990; Oluwatosin et al. 1998; Yoshida et al. 2000; Iwaki et al. 2003). *Vma* mutants carry mutations in subunits of the vacuolar H⁺-ATPase (an enzyme responsible for the acidification of vacuolar contents and maintenance of intracellular pH) and class C and class D *vps* mutants display defects in vacuole morphogenesis (Rothman et al. 1986; Robinson et al. 1988). These mutants are also sensitive to environmental manipulations such as external pH and sodium orthovanadate (Banta et al. 1988; Kitamoto et al. 1988; Klionsky et al. 1990; Takeshige et al. 1992; Iwaki et al. 2003). Therefore, the data in *S. pombe* suggest that Ppt1p functions in the vacuole, just as it functions in the analogous structure (lysosome) of mammalian cells.

The observed proteolytic processing of the Pdf1p fusion protein in *S. pombe* is also entirely consistent with the known subcellular compartmentalization of Ppt1p and Dolpp1p in mammalian cells. As described earlier, Ppt1p is a resident soluble lysosomal enzyme in higher organisms that traffics through the classical mannose 6-phosphate receptor pathway (Verkruyse et al. 1996), whereas Dolpp1p is a resident ER protein (Fernandez et al. 2001; Rush et al. 2002). Therefore, the data are consistent with a model that in *S. pombe*, the Pdf1p fusion protein is directed into the secretory pathway by virtue of the Ppt1p signal sequence, with appearance of the Ppt1p domain on the lumenal side, followed by cotranslational

incorporation of Dolpp1p into the ER membrane. The fusion protein would then become available for processing by Krp1p (or a related enzyme) and the Ppt1p domain would be free for transport to the vacuole.

Whether Pdf1p is indeed a physiological substrate for Krp1p remains to be determined experimentally. Deletion of *Krp1* in *S. pombe* is lethal (Powner et al. 1998), and as deletion of Dolpp1p is also lethal, one may speculate that lack of processing of Dolpp1p by Krp1p is responsible for the lethality in *Krp1* null strains. (Of note, Dolpp1p processing mutants created in this study were viable, but the mutants appeared to be leaky, because small amounts of processed Ppt1p were detectable on longer exposures).

The translation of Pdf1p as a single polypeptide suggests that there may be an advantage in coordinately regulating levels of Ppt1p and Dolpp1p in *S. pombe*. In mammalian cells, a number of lysosomal enzymes are coordinately upregulated in a compensatory fashion under conditions of lysosomal dysfunction (Cataldo et al. 1991; Kopacek et al. 2000; Tyynela et al. 2000).

Studies in lower organisms, particularly yeast, have provided surprising insights into human biology, even in the area of human neurodegenerative disease (Sherman et al. 2003). The two yeast models of Batten disease have provided evidence for abnormal vacuolar function due to lack of the relevant disease proteins and have begun to implicate abnormalities in pH homeostasis in the pathogenesis of these disorders, with implications for therapy. Future work in these genetically tractable organisms may therefore provide further insights into the pathogenesis of Batten Disease.

CHAPTER THREE

Cloning and characterization of mammalian *DOLPP1*

3.1 Introduction

The multisubunit oligosaccharyltransferase (OST) complex (Silberstein *et al.* 1996) catalyzes the transfer of Glc₃Man₉GlcNAc₂ from dolichyl pyrophosphate (Dol-P-P) to asparagine residues of the *N*-glycosylation in the consensus sequence (Asn-Xxx-Ser/Thr) during the co-translational *N*-glycosylation of nascent polypeptides in yeast and mammalian cells (Herscovics *et al.* 1993; Burda *et al.* 1999; Schenk *et al.* 2001). During the process, Dol-P-P is released on the luminal surface of the endoplasmic reticulum (ER). In order for Dol-P-P to be re-utilized as a glycosyl carrier lipid for additional rounds of lipid intermediate biosynthesis, it has to be converted to dolichyl phosphate (Dol-P) and translocated to the cytoplasmic face of the ER (Schenk *et al.* 2001). Although it is possible that Dol-P-P, or perhaps Dol-P, diffuses transversely from the luminal leaflet to the cytoplasmic face by a protein-mediated mechanism, it is hypothesized that it is dephosphorylated on the luminal surface to form free dolichol that could more readily diffuse back to the cytoplasmic leaflet. Then, free dolichols in the cytoplasm would be re-phosphorylated by dolichol kinase (Allen *et al.* 1978; Fernandez *et al.* 2001). It has been shown that the *CWH8* gene in *Saccharomyces cerevisiae* encodes a Dol-P-P phosphatase that actively converts Dol-P-P to Dol-P (Fernandez *et al.* 2001). Moreover, the yeast Dol-P-P phosphatase is recovered in crude microsomal fractions, but its subcellular location has not been established. Although it has been reported that crude microsomal fractions from a variety of mammalian cells contain

enzymes that can hydrolyze exogenous Dol-P-P, the identity, specificity and exact subcellular location of the enzymes catalyzing the hydrolysis of Dol-P-P have not been established (Scher *et al.* 1984a; Wolf *et al.* 1991; Toke *et al.* 1998; Faulkner *et al.* 1999; Toke *et al.* 1999; Fernandez *et al.* 2001; Schenk *et al.* 2001).

In this chapter, I will present the data of cloning and characterization of mammalian ortholog of *CWH8*, including a subcellular localization study. The identification of the mammalian ortholog of *CWH8* as a Dol-P-P pyrophosphate phosphatase is based on its ability to complement defects in growth and protein *N*-glycosylation in the *cwh8Δ* mutant and to prevent the accumulation of Dol-P-P in the mutant cells (van Berkel *et al.* 1999; Fernandez *et al.* 2001). These studies were done in collaboration with Dr. Skip Waechter's group at University of Kentucky. The mammalian ortholog gene of *CWH8* is then renamed as mouse *DOLPP1* (dolichol pyrophosphate phosphatase 1). Polyclonal antibody against a synthetic peptide corresponding to amino acid residues (86-105) of mouse *DOLPP1* has been generated. This polyclonal antibody (anti-mDOLPP1) was utilized in subcellular localization studies.

3.2 Experimental Procedures

3.2.1 Materials

Plasmid YEp352 containing the yeast gene *CWH8* coding sequence and 240 bp of 5'-flanking sequence was a gift from Drs. Fabiana Fernandez and Markus Aebi (ETH, Zurich, Switzerland). Yeast strains W303-1A, *cwh8Δ*, and *lpp1Δ/dpp1Δ* were the generous gifts from Dr. George Carman, Department of Food Science, Rutgers University, New Brunswick,

NJ. *n*-Octyl- β -D-glucopyranoside was purchased from Calbiochem-Novabiochem. Triton X-100 was from Pierce. Trichloroacetonitrile, tetrabutylammonium hydroxide, and anhydrous acetonitrile were obtained from Aldrich. Nycodenz, dioleoylphosphatidic acid (lot number 129F8359), and diolein (D-8894) were obtained from Sigma. Dolichol (C95) was a generous gift from Dr. M. Mizuno, Kuraray Chemical Co. (Okayama, Japan). Carrier-free [^{32}P] phosphoric acid was purchased from American Radiolabeled Chemicals (St. Louis, MO). Econo-safeTM biodegradable scintillation counting mixture is a product of Research Products International (Mount Prospect, IL). Yeast nitrogen base, yeast extract, and BactoPeptone are products of BD Biosciences. Casamino acid is a product of Fisher. Antibodies were obtained from the following commercial sources and used according to instructions from the supplier: rabbit anti-calnexin polyclonal antibody and mouse anti-KDEL monoclonal antibody (StressGen Biotechnologies, Victoria, British Columbia, Canada); mouse anti-KDEL receptor monoclonal antibody, mouse anti- β -COP monoclonal antibody, horseradish peroxidase-conjugated sheep anti-rabbit IgG, horseradish peroxidase-conjugated sheep anti-mouse IgG (Amersham Biosciences); and fluorescein isothiocyanate-conjugated goat anti-rabbit IgG and Texas Red-conjugated goat anti-mouse IgG (Molecular Probes, Eugene, OR). Anti-CPY antiserum was generously provided by Dr. Neta Dean, State University of New York, Stony Brook, NY. All other chemicals and reagents were purchased from standard commercial sources.

3.2.2 Affinity-purified rabbit anti-Dolpp1p antibodies and immunoblotting

Three New Zealand White rabbits were each immunized with 300 µg of a synthetic peptide corresponding to amino acid residues 86-105 of mouse Dolpp1p coupled to keyhole limpet hemocyanin as described previously (Camp *et al.* 1994). The antigen was injected intradermally in Freund's complete adjuvant, and rabbits were boosted three times at 3-week intervals with 300 µg of peptide in Freund's incomplete adjuvant. An IgG fraction was prepared from preimmune and immune serum by specific binding to protein A-Sepharose CL-4B (Amersham Biosciences). IgG was affinity-purified by specific binding to a column consisting of the Dolpp1p peptide cross-linked to SulfoLink coupling gel (Pierce). For analysis of *DolPPI* expression by immunoblotting, samples were analyzed by electrophoresis in 15% SDS-PAGE gels and immunoblotting essentially as described (Verkruyse *et al.* 1997). Filters were blocked for 1 h with Sea Block (East Coast Biologics, North Berwick, ME) and washed in PBS-T (0.25% (v/v) Tween 20 in phosphate-buffered saline) followed by incubation for 2 h with rabbit anti-Dolpp1p polyclonal antibody (1 µg/ml). The filters were washed with PBS-T and incubated for 45 min in a solution containing horseradish peroxidase-conjugated secondary antibody (sheep anti-rabbit IgG, Amersham Biosciences) diluted 1:2500 in PBS-T. The filters were washed and developed using ECL chemiluminescence reagents (Amersham Biosciences).

3.2.3 Preparation of radiolabeled phosphorylated lipid substrates

$[^{32}\text{P}]\text{PA}$, $[^{32}\text{P}]\text{Dol-P}$, $[\alpha, \beta\text{-}^{32}\text{P}]\text{Dol-P-P}$, and $[\beta\text{-}^{32}\text{P}]\text{Dol-P-P}$ were chemically synthesized in anhydrous acetonitrile from the appropriate lipid using $[^{32}\text{P}]\text{tetrabutylammonium phosphate}$ and trichloroacetonitrile as described by Danilov *et al.*

(Danilov *et al.* 1989). Unlabeled polyisoprenyl phosphates were synthesized using tetrabutylammonium phosphate. Synthetic substrates were purified by preparative thin layer chromatography on Baker Si250 thin layer plates developed in $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}/\text{NH}_4\text{OH}$ (65:35:6:1, v/v).

3.2.4 Northern blotting

Plasmid and genomic DNA preparation, restriction enzyme digestion, and DNA ligations were performed by standard methods (Sambrook *et al.* 1989). Transformation of yeast and *Escherichia coli* were performed as described (Sambrook *et al.* 1989; Schiestl *et al.* 1989). For blot hybridization of RNA, total RNA was isolated from mouse tissues as described (Gupta *et al.* 2001). Blots were pre-hybridized for 30 min at 65 °C in Rapid-Hyb buffer (Amersham Biosciences), followed by hybridization with a random hexamer-primed ^{32}P -labeled mouse cDNA fragment corresponding to the entire 717-bp coding region of DolPP1 for 3 h at 65 °C. The blots were washed in $2\times$ SSC ($1\times$ SSC = 150 mM NaCl and 15 mM sodium citrate (pH 7)), 0.1% SDS at ambient temperature for 30 min, followed by stringent washes in $0.5\times$ SSC, 0.1% SDS at 65 °C for 15 min and in $0.1\times$ SSC, 0.1% SDS at 65 °C for 15 min.

3.2.5 Yeast culture

Yeast cultures were grown at 30 °C in either 1% yeast extract, 2% BactoPeptone, and 2% dextrose or in yeast nitrogen base (6.7 g/liter), 50 mM sodium succinate (pH 5.0), 2% dextrose, amino acids (25 mg/liter), and purine and pyrimidine bases (25 mg/liter) as required to meet auxotrophic requirements for selective growth. Yeast transformants were screened on

2% agar plates containing 6.7 g/liter yeast nitrogen base, 0.5% casamino acids, 50 mM sodium succinate (pH 5.0), 2% dextrose, and 25 mg/liter adenine or leucine as required.

Yeast microsomal fractions for the routine analysis of lipid phosphatase activities were prepared exactly as described previously (Fernandez *et al.* 2001). Assays of Dol-P-P, Dol-P, and PA phosphatase activities were performed as described previously (Scher *et al.* 1984a; Scher *et al.* 1984b).

3.2.6 Measurement of cellular levels of Dol-P and Dol-P-P in yeast cells

Yeast cells (1 liter) were grown in YPD containing 2% dextrose to 1-4 A_{600} and collected by centrifugation at $1,000 \times g$, 20 min. The cells were resuspended in distilled water, sedimented again, resuspended in distilled water to 200 A_{600} /ml, and incubated for 30 min at 30 °C in 50 mM Tris-HCl (pH 7.4), 10 mM $MgCl_2$ containing 1 mg/ml lyticase (Sigma). The yeast spheroplasts were sedimented at $1,000 \times g$ for 20 min; the supernatant was decanted, and the pellet was mixed vigorously with 40 volumes of $CHCl_3/CH_3OH$ (2:1, v/v). Dol- ^{32}P and Dol-P- ^{32}P (5,000 cpm of each) were added as recovery markers, and the insoluble material was sedimented in a clinical centrifuge. The organic layer was removed and reserved on ice. The insoluble pellet was sequentially extracted twice with 5 ml of $CHCl_3/CH_3OH$ (2:1 v/v) and twice with 5 ml of $CHCl_3/CH_3OH/H_2O$ (10:10:3, v/v). The organic extracts were combined, taken to dryness by rotary evaporation under reduced pressure at 30 °C, and then saponified in 1 ml of toluene/ CH_3OH (1:1, v/v) containing 0.1 M KOH on ice for 30 min. Following saponification, the reaction was neutralized with acetic acid, diluted with 5 ml of $CHCl_3/CH_3OH$ (2:1 v/v), and partitioned with 1 ml of water. The

aqueous layer was discarded, and the organic phase was subsequently partitioned twice with 1 ml of $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ (3:48:47, v/v). The organic phase was dried under a stream of N_2 gas and redissolved in 0.2 ml of $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ (10:10:3, v/v). Dol-P and Dol-P-P in the organic extracts were separated by ion exchange chromatography on a 20-ml column of DEAE-650M (Toyopearl, Supelco, Bellefonte, PA) equilibrated with $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ (10:10:3, v/v) and eluted with a linear gradient of 0 to 0.2 M ammonium acetate (60 ml). The fractions containing Dol-P and Dol-P-P were pooled separately and supplemented with CHCl_3 and water to give a final composition of $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ (3:2:1, v/v). The phases were separated by a brief centrifugation, and the aqueous layer was discarded. The organic layer was then partitioned once with 1/5 volume of $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ (3:48:47, v/v), taken to dryness under a stream of N_2 gas, and redissolved in a small volume of $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$ (10:10:3, v/v). Aliquots representing equivalent portions of the initial extracts were spotted on 10×20 -cm Baker Si250 Silica Gel thin layer plates and developed in $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}/\text{NH}_4\text{OH}$ (65:35:6:1, v/v). Following chromatography, the thin layer plates were allowed to air dry and were visualized by staining with anisaldehyde (Dunphy *et al.* 1967). The migration positions of radioactive standards were determined with a Bioscan System 200 Imaging Scanner (Bioscan Inc. Washington, D. C.).

3.2.7 Expression of pCHA7/*DOLPP1* in COS cells

To construct a Dolpp1p transient expression plasmid for mammalian COS cells, the expressed sequence tag division of GenBankTM was searched for clones homologous to *S. cerevisiae* Cwh8p, and yielded IMAGE clone 1974625, GenBankTM accession number

AI876279. (This clone was obtained independently of gene 2-23 sequence described above.)

Both strands of the cDNA were sequenced, which revealed that the clone was incomplete at the 5' end. Therefore, a 5'-RACE procedure was employed using 1 µg of mouse total brain mRNA and a SMART RACE cDNA Amplification Kit (Clontech Laboratories, Inc., Palo Alto, CA). Briefly, Moloney murine leukemia virus-reverse transcriptase Superscript II (Invitrogen) was used to perform the reverse transcription according to the supplier's protocol. PCR was performed using the supplied universal primer mix, a gene-specific primer (5'-CTGGGAATGGCTGGAGGGCATCCCG-3'), and a nested primer (5'-CGCCCTGATTCACTGCCAGTCCCC-3') to obtain the 5' terminus of mouse *DOLPPI* cDNA. The PCR was performed using a PerkinElmer Life Sciences GeneAmp System 9600 using the Advantage 2 PCR kit (Clontech Laboratories, Inc., Palo Alto, CA) under conditions suggested by the supplier. The resulting fragment was subcloned into the plasmid pGEM-T-Easy (Promega, Madison, WI), sequenced, and shown to be complete at the 5' end. The entire open reading frame was then amplified from total mouse brain cDNA using primers corresponding to sequences within the 5'-RACE product and mouse expressed sequence tag IMAGE clone 1974625 (5'- ATGGCAGCGGACGGACAGTGC-3' and 5'-TCACTGCAGTTTTGTTCCAAG-3'). PCR conditions for the amplification consisted of the following: 95 °C, 5 min, one cycle; 94 °C, 30 s, 68 °C to 58 °C ("touch down" protocol), 30 s, 72 °C, 1 min for 10 cycles; 94 °C, 30 s, 58 °C, 30 s, 72 °C, 1 min for 25 cycles; 72 °C, 10 min. The resulting PCR product was subcloned into pCHA7 using *SalI* and *BamHI* restriction sites at the 5' and 3' ends of the insert, respectively (Cha *et al.* 2000). The construct

was verified by sequencing, and the open reading frame was found to be 100% identical to GenBankTM AB030189, which was deposited subsequently (Inoue *et al.* 2000).

Simian COS-7L cells were maintained in Dulbecco's modified Eagle's medium (high glucose), supplemented with 10% (v/v) fetal bovine serum, 100 units/ml penicillin, 100 µg/ml streptomycin, and 0.25 µg/ml amphotericin B. Cells were plated on Day 0 in 100-mm dishes and were transiently transfected on Day 1 using 6 µg of DNA (pCHA7/DOLPP1) and 18 µl of FuGEN 6 reagent (Roche Molecular Biochemicals) per plate. The cells were harvested 48 h post-transfection into ice-cold phosphate-buffered saline and pelleted at low speed. Cell pellets were resuspended in a homogenization buffer containing 50 mM Tris-HCl (pH 7.5), 0.25 mM sucrose, 5 mM EDTA, and 5 mM 2-mercaptoethanol and sonicated briefly. Nuclei and intact cells were removed by centrifugation at $500 \times g$ for 5 min at 4 °C. The postnuclear supernatant was further centrifuged at $100,000 \times g$ for 1 h at 4 °C in a Beckman Optima TLX ultracentrifuge. The resulting supernatant (S100) was reserved, and the membrane pellet (P100) was washed once and resuspended in homogenization buffer for immunoblotting or in 10 mM HEPES (pH 7.0), 0.25 M sucrose at a concentration of 10 mg of protein per ml for analysis of enzyme activity.

3.2.8 Subcellular localization of Dolpp1p

COS-7L cells (six 100-mm dishes) were transfected using pCHA7/DOLPP1 as described above and washed twice in a buffer consisting of 10 mM triethanolamine, 10 mM acetic acid, 250 mM sucrose, 1 mM EDTA, and 1 mM dithiothreitol. Cells were harvested with a rubber policeman in 800 µl of buffer containing 10 µg/ml each of chymostatin,

leupeptin, and pepstatin and homogenized by 15 passages through a 25-gauge needle on a 1-ml syringe. Nuclei and intact cells were removed by microcentrifugation at $1,200 \times g$ for 5 min at 4 °C. The postnuclear supernatant was loaded on preformed Nycodenz gradients prepared exactly as described (Rickwood *et al.* 1982). Briefly, linear Nycodenz gradients were prepared for the Beckman SW 41 Ti rotor from initial discontinuous gradients (24, 19, 15, and 10% Nycodenz in 10 mM Tris-HCl (pH 7.4), 3 mM KCl, and 1 mM EDTA) that were allowed to diffuse in a horizontal position for 45 min at room temperature and then centrifuged for 4 h at 37,000 rpm in a Beckman L8-M ultracentrifuge to generate a nonlinear density gradient profile. The postnuclear supernatant was loaded on top of the gradients and centrifuged for 1.5 h at 37,000 rpm. Fifteen fractions were collected, and aliquots of each fraction were subjected to electrophoresis on SDS-PAGE gels. The distribution of Dolpp1p, calnexin (ER marker), KDEL receptor (Golgi marker), and β -COP (Golgi marker) in the gradients was determined by immunoblotting using ECL chemiluminescence reagents (Amersham Biosciences).

3.2.9 Immunofluorescence

COS-7L cells were grown on 12-mm diameter coverslips and transfected with pCHA7/DOLPP1 using FuGEN 6 as described above. At 48 h post-transfection, the cells were fixed for 15 min in 4% formaldehyde and permeabilized for 10 min with 0.05% Triton X-100 at room temperature. The cells were doubly stained using the rabbit anti-Dolpp1p antibody and either the anti-KDEL monoclonal antibody or anti-KDEL receptor monoclonal antibody. The secondary antibodies used were fluorescein isothiocyanate-conjugated goat

anti-rabbit IgG and Texas Red-conjugated goat anti-mouse IgG. Immunofluorescence was visualized under a Zeiss Axiophot immunofluorescence microscope.

3.2.10 Preparation of sealed microsomal vesicles and general analytical methods

Sealed microsomal vesicles were prepared from the pertinent yeast strains and evaluated for integrity as described previously (Rush *et al.* 1998; Fernandez *et al.* 2001). Protein was determined by the method of Rodriguez-Vico *et al.* using a commercial protein assay reagent (BCA, Pierce) and bovine serum albumin as standard. Lipid-phosphorus analysis was according to Bartlett (Bartlett 1959; Rodriguez-Vico *et al.* 1989). Radioactivity was measured by liquid scintillation spectrometry in a Packard Tri-Carb TR-2100 Liquid Scintillation Analyzer (Packard Instrument Co., Meriden, CT) in the presence of Econo-Safe Biodegradable Counting Mixture (Research Products International, Mount Prospect, IL).

3.3 Results

3.3.1 Mammalian cells express an ortholog of the yeast *CWH8* gene

To find a mammalian ortholog of *CWH8*, the GenBankTM expressed sequence tag division was searched for clones orthologous to *S. cerevisiae* Cwh8p, yielding IMAGE clone 1974625, GenBankTM accession number AI876279. As described in Experimental Procedures, the full length cDNA clone of mouse *DOLPPI* was obtained. Its deduced amino acid sequences are 29.8% identical and 49.4% strongly similar to sequences of yeast Cwh8p. In addition, Dolpp1p contains the consensus lipid-phosphate phosphatase motif, suggesting that Dolpp1p is the mammalian ortholog of yeast *CWH8* (Stukey *et al.* 1997).

Figure 3.1 RNA blot hybridization of *DOLPP1* RNA from mouse tissues. Total RNA (20 μ g) from various tissues was subjected to electrophoresis and transferred to a nylon membrane. Hybridization was performed using a 32 P-labeled *DOLPP1* cDNA probe (*upper panel*) followed by washing as described under "Experimental Procedures." The filter was exposed to Amersham Biosciences Hyperfilm MP film with an intensifying screen at -85°C for 4 days. The integrity of RNA in each lane was demonstrated by stripping and reprobing the filter with a 32 P-labeled cDNA probe encoding mouse cyclophilin A (*lower panel*).

The *DOLPP1* mRNA was found to be widely expressed in various mouse tissues as assessed by RNA blotting (Figure 3.1). A single transcript migrating at 2.0 kb was observed in all tissues examined, with highest expression in brain, kidney, lung, and intestine and low but detectable levels in liver, spleen, and uterus. The broad tissue distribution is consistent with the ER Dol-P-P phosphatase having an essential function in the lipid intermediate pathway for protein *N*-glycosylation in all mammalian cells.

3.3.2 Overexpression of Dolpp1p corrects defects in growth rate and N-glycosylation of CPY in the *cwh8Δ* mutant

The mutant yeast strain, *cwh8Δ*, grows at an abnormally slow rate and exhibits a defect in protein N-glycosylation (van Berkel *et al.* 1999; Fernandez *et al.* 2001). To

determine whether expression of mammalian *DOLPP1* corrects the growth deficiency of the *cwh8Δ* yeast strain, the *DOLPP1* gene was subcloned into YEp352 under the control of the putative yeast *CWH8* promoter and transformed into *cwh8Δ*. The effect on rate of growth in complete media was then assessed. As shown in Table 3.1, the cell density of wild type yeast cultures typically doubles approximately every 2 h, whereas the doubling time ($T_{2\times}$) for *cwh8Δ* was ~4 h. Overexpression of *DOLPP1* in *cwh8Δ* reduces the doubling time to 3 h, similar to the effect of transformation with YEp352 containing the yeast *CWH8* gene ($T_{2\times} = 2.5$ h).

Table 3.1 Overexpression of either *DOLPP1* or *CWH8* partially restores the normal rate of growth in the *cwh8Δ* yeast mutant

Yeast strain	Doubling time (h)
Wild type	1.9
<i>cwh8Δ</i>	4.0
<i>cwh8Δ/DOLPP1</i>	3.0
<i>cwh8Δ/CWH8</i>	2.5

As reported previously, mutation of the *CWH8* gene in yeast results in defects in protein *N*-glycosylation, as assessed by *N*-glycosylation of carboxypeptidase Y (CPY) (van Berkel *et al.* 1999; Fernandez *et al.* 2001)(Figure 3.2). Although SDS-PAGE of wild type yeast extracts revealed a single protein band corresponding to mature, fully *N*-glycosylated CPY (Figure 3.2, *lane 1*), extracts from the *cwh8Δ* mutant contain several bands

corresponding to underglycosylated isoforms of CPY (Figure 3.2, *lane 2*). (The migration positions of CPY lacking 1-4 oligosaccharide chains are indicated by the *arrows*.) Expression of YEp352 carrying either the *DOLPP1* gene or the yeast *CWH8* gene restored full glycosylation to CPY (Figure 3.2, *lanes 3 and 4*, respectively).

Figure 3.2 Overexpression of DOLPP1 cDNA corrects hypoglycosylation of CPY in the yeast *cwh8Δ* mutant. Total cell extracts from the various yeast strains were separated by SDS-PAGE and analyzed by Western blotting using α -CPY serum as described previously (56). Lane 1, wild type; lane 2, *cwh8Δ*; lane 3, *cwh8Δ/DOLPP1*; and lane 4, *cwh8Δ/CWH8*. The positions of mature CPY and underglycosylated isoforms are indicated.

3.3.3 Overexpression of either Dolpp1p or Cwh8p reverses the accumulation of Dol-P-P in the *cwh8Δ* mutant

Abnormally high levels of Dol-P-P accumulate in *cwh8Δ* yeast cells, due to a lack of the Dol-P-P phosphatase activity responsible for the hydrolysis of the Dol-P-P released

during the transfer of the precursor oligosaccharide from $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-Dol}$ to nascent polypeptides in the lumen of the ER (Fernandez *et al.* 2001).

Figure 3.3 Overexpression of Dolpp1p corrects Dol-P-P accumulation in the yeast *cwh8Δ* mutant. Dol-P-P was extracted from either wild type (lane 1), *cwh8Δ* (lane 2), *cwh8Δ/DOLPP1* (lane 3), or *cwh8Δ/CWH8* yeast strains and chromatographed on Baker Si250 Silica Gel thin layer plates as described under "Experimental Procedures." Dol-P-P was visualized by anisaldehyde staining (Dunphy *et al.* 1967).

To determine whether overexpression of Dolpp1p in *cwh8Δ* will restore normal Dol-P-P levels, total lipid extracts were prepared from either wild type, *cwh8Δ* plus YEp352, *cwh8Δ* plus YEp352/yPro-*DOLPP1*, or *cwh8Δ* plus YEp352/*CWH8* yeast cells and analyzed for Dol-P-P (Figure 3.3, panel A, lanes 1-4). As reported earlier (Fernandez *et al.* 2001), the lipid extracts from *cwh8Δ* cells (Figure 3.3, panel A, lane 2), contained a prominent anisaldehyde-positive compound with the chromatographic mobility of standard Dol₇₅-P-P.

In contrast to this result, virtually no Dol-P-P was detected in extracts from wild type cells (Figure 3.3, panel A, lane 1) or from *cwh8Δ* yeast cells expressing either the *DOLPP1* gene (Figure 3.3, panel A, lane 3) or the *CWH8* gene (Figure 3.3, panel A, lane 4). To confirm the identity of the anisaldehyde-positive compound as Dol-P-P, this lipid was quantitatively converted to a product chromatographically identical to Dol75-P by mild acid hydrolysis (2 h at 80 °C in CHCl₃, CH₃OH, 2 N HCl, 10:10:3, v/v). It should be noted that the levels of Dol-P in the various yeast strains were not significantly different (Figure 3.3; panel B, lanes 1-4).

3.3.4 Increase in Dol-P-P phosphatase activity upon overexpression of Dolpp1p in COS cells

The results described above (obtained from collaborative work with Dr. Waechter's group) indicate that the *DOLPP1* gene encodes a functional ortholog of the yeast Cwh8p. To explore the properties of the *DOLPP1* expressed in mammalian cells, the full-length mouse brain *DOLPP1* cDNA was inserted into the eukaryotic expression vector pCHA7 to yield the plasmid pCHA7/*DOLPP1*. Microsomal fractions were prepared from the COS cells after transient transfection with either pCHA7/*DOLPP1* or vector alone. Phosphatase reaction mixtures contained microsomes from COS cells (10 µg of protein), 10 mM EDTA, 0.6% n-octylglucoside, 25 mM citrate-sodium phosphate (pH 7), and 20 µM of substrate in a total of 0.02 ml. Three different substrates were assayed; [β -³²P] Dol-P-P, [³²P] Dol-P or [³²P] PA. The reaction mixture was incubated with the substrate for 5 min at 30 °C and the rates of dephosphorylation of each substrate were assayed as described previously (Scher et al. 1984a; Scher et al. 1984b). As shown in Table 3.2, a substantial increase (12-16-fold) of Dol-

P-P phosphatase activity was seen compared with identical microsomal fractions from cells transfected with the empty vector alone. It is noteworthy that no concomitant increase in Dol-P or PA dephosphorylation was observed, corroborating the specificity for Dol-P-P.

Table 3.2 Dol-P, Dol-P-P and PA phosphatase activities assayed in microsomes from COS cell lines expressing Dolpp1p.

Yeast strain	Phospholipid substrate (nmol/min/mg)		
	Dol-P-P	Dol-P	PA
COS cells	1	<0.01	0.03
COS cells	0.8	<0.01	0.06
COS(DOLPP1)	16.2	0.03	0.09
COS(DOLPP1)	12.2	<0.01	0.08

3.3.5 Expression and Subcellular Localization of Dolpp1p in COS Cells

Although mutations in the *CWH8* gene affect the rate of lipid intermediate synthesis and protein *N*-glycosylation in the ER, the precise subcellular location of the yeast enzyme had not been firmly established. Soluble (S100) and particulate (P100) fractions from *DOLPP1*-transfected COS cells were analyzed by SDS-PAGE and immunoblotting using a rabbit polyclonal antibody raised against a Dolpp1p peptide (Figure 3.4). This analysis revealed a single band in the P100 fraction (Figure 3.4, *lane 4*) at a M_r of 27 kDa in accord with the molecular mass of Dolpp1p predicted from the *DOLPP1* cDNA sequence

(27.1 kDa). No bands were visible in the S100 fraction or the fractions from the vector-transfected cells (Figure 3.4, *lanes 1-3*).

Figure 3.4 Dolpp1p expressed in COS cells is membrane-associated. COS-7L cells were transfected with pCHA7 (*lanes 1 and 3*) or pCHA7/DOLPP1 (*lanes 2 and 4*) and harvested 48 h later. Cells were sonicated briefly and centrifuged at $100,000 \times g$ to obtain a soluble fraction (*S100*, *lanes 1 and 2*) and a particulate fraction (*P100*, *lanes 3 and 4*). A single band appears exclusively in the particulate fraction (*lane 4*) as visualized by immunoblotting using a rabbit anti-Dolpp1p peptide antibody. The visualized band corresponds to the predicted molecular mass of Dolpp1p (27 kDa).

To determine further the subcellular location of Dolpp1p, transfected COS cells were fractionated on nonlinear Nycodenz gradients, using a method previously developed to provide effective separation of ER and Golgi complex proteins (Rickwood *et al.* 1982). As shown in Figure 3.5, >95% of the immunoreactivity sedimented to the bottom of the gradient (*upper panel*), co-sedimenting with calnexin, a well established ER marker. A much smaller amount was found at the top of the gradient co-fractionating with the Golgi markers, KDEL

receptor and β -COP (Figure 3.5). The minor immunoreactivity in Golgi shown in Figure 3.5 was not observed in every experiment and seemed to correlate with higher levels of Dolpp1p expression.

Figure 3.5 Subcellular localization of Dolpp1p on Nycodenz density gradients. COS-7L cells were transfected with pCHA7/DOLPP1 and cell homogenates separated on preformed Nycodenz gradients. Fractions along the gradient were analyzed by immunoblotting using anti-Dolpp1p anti-peptide antibodies and other markers as indicated. Marker proteins were calnexin (ER membrane marker), β -COP (Golgi marker), and KDEL receptor (Golgi marker). A predominantly ER localization for Dolpp1p was observed (top panel). The results illustrated in this figure are representative of three separate experiments.

A reticular and nuclear envelope pattern, which is characteristic of ER localization, was observed when COS cells overexpressing *DOLPP1* were examined by immunofluorescence microscope using a specific Dolpp1p antibody (Figure 3.6). This pattern essentially completely overlapped with the ER marker (KDEL, *upper panel*) and showed no overlap with a Golgi marker (KDEL receptor, *lower panel*).

Figure 3.6 ER localization of Dolpp1p by immunofluorescence in fixed and permeabilized COS-7L cells. COS-7L cells were transfected with pCHA7/DOLPP1 and simultaneously stained with anti-Dolpp1p antibodies (*green*, *A* and *D*) and one of two markers, anti-KDEL antibody (ER marker, *red*, *B* and *C*) or anti-KDEL receptor (Golgi marker, *red*, *E* and *F*). Dolpp1p (*green*) shows a reticulated and nuclear envelope pattern typical of ER localization, an impression that is confirmed by the overlapped images (*merge*, *C*). Dolpp1p staining was distinct from Golgi staining (*F*). Weak nuclear labeling was evident in some preparations and was deemed nonspecific because it appeared in the presence of either anti-Dolpp1p or non-immune antibodies (not shown). Experiment shown is one of two yielding similar results.

3.3.6 Topological Orientation of the Active Site of Dolpp1p

To determine whether the active site of Dolpp1p faces the lumen of the ER or the cytoplasm, protease-sensitivity studies were conducted on the Dol-P-P phosphatase activity in intact and unsealed ER vesicles from the *lpp1 Δ /dpp1 Δ /DOLPP1* yeast strain. When detergent-disrupted ER vesicles (Table 3.3) were treated with trypsin, the Dol-P-P phosphatase activity was extensively inactivated (74.8% of control). However, the phosphatase activity was found to be relatively resistant to proteolysis in intact ER vesicles

(87.5% of control). Separate pilot experiments employing latency of glucosidase I/II established that the sealed vesicles used in this experiment were >98% intact throughout the time of incubation and that 0.2% Triton X-100 was sufficient to unseal >95% of the yeast ER vesicles (Rush *et al.* 1998). Thus, it appears that the mammalian Dol-P-P phosphatase has a trypsin-sensitive site, perhaps part of the reactive site of the enzyme, which is lumenally oriented, as in the yeast enzyme.

Table 3.3 Effect of trypsinization on Dol-P-P phosphatase activity in intact and disrupted microsomal vesicles from *lpp1Δ/ dpp1Δ/DOLPP1* yeast

Vesicle treatment	Time of exposure to trypsin (min)	Dol-P-P phosphatase activity	
		(nmol/min/mg)	(% control)
None	0	3.3	100
None	60	2.9	87.5
Unsealed with 0.2% Triton X-100	0	3.7	100
Unsealed with 0.2% Triton X-100	60	0.98	26.2

3.3.7 Dolpp1p activity in *PPT1* knockout mouse brain

To further explore the functional relationship between PPT1 and DOLPP1, I prepared microsomal fractions from brain tissues of wild type, PPT1 and PPT2 knockout mice and assayed Dol-P-P phosphatase activity. Three different substrates were assayed; [β - 32 P] Dol-P-P, [32 P] Dol-P or [32 P] PA. The reaction mixture was incubated with the substrate for 10 min at 30 °C except for [β - 32 P] Dol-P-P which was incubated for 3 min at 30 °C, and the

rates of dephosphorylation of each substrate were assayed as described previously (Scher *et al.* 1984a; Scher *et al.* 1984b).

As shown in Table 3-4, Dolpp1p activity was decreased in the brain microsomes of *PPT1* knockout mouse compared to wild type and *PPT2* knockout mouse, indicating loss of PPT1 activity somehow affected the Dolpp1p activity in the brain.

Table 3.4 Dol-P, Dol-P-P and PA phosphatase activities assayed in microsomes from wild type, *PPT1* and *PPT2* knockout mice brain.

Mouse strain	Phospholipid substrate (nmol/min/mg)		
	Dol-P-P	Dol-P	PA
Wild type brain	0.128	0.107	0.129
<i>PPT1</i> knockout brain	0.025	0.138	0.160
<i>PPT2</i> knockout brain	0.089	0.101	0.131

3.4 Discussion

The *CWH8* gene in *S. cerevisiae* has been shown to encode a Dol-P-P-specific pyrophosphate phosphatase that was proposed to function in a model for the recycling of the carrier lipid (Fernandez *et al.* 2001). This chapter describes the identification and characterization of a mammalian ortholog of the yeast *CWH8* gene, *DOLPP1*, from the GenBankTM expressed sequence tag (EST) division.

Although there have been reports describing Dol-P-P/Dol-P phosphatase activities in crude microsomal fractions from various mammalian tissues, the exact number, location, and

specificity have not been rigorously defined (Scher *et al.* 1984a; Wolf *et al.* 1991; Faulkner *et al.* 1999; Fernandez *et al.* 2001). Previous studies have been complicated by an inability to study the enzymatic properties of these proteins independent of the activities of other contaminating phosphatases. Expression of Dolpp1p in the *lpp1*Δ/*dpp1*Δ yeast strain has allowed characterizing the brain Dol-P-P phosphatase in the absence of other endogenous lipid phosphatase activities hydrolyzing Dol-P-P and Dol-P. As collaborative work with Dr. Waechter's group at University of Kentucky, the comparisons reported in Tables 3.2 show that expression of Dolpp1p in COS cells results in a substantial and highly specific increase in Dol-P-P phosphatase activity.

DOLPP1 shares a high degree of sequence identity with *CWH8* and is shown to be a functional ortholog in the *cwh8*Δ mutant yeast strain. This conclusion is based on the following observations that overexpression of mouse *DOLPP1* in *cwh8*Δ yeast cells: 1) complements the growth defect; 2) corrects the deficiency in protein *N*-glycosylation; and 3) reverses the accumulation of Dol-P-P resulting from defective Dol-P-P phosphatase activity. Moreover, as noted above, expression of the *DOLPP1* gene in the *lpp1*Δ/*dpp1*Δ yeast strain, or mammalian COS cells produces large increases in Dol-P-P phosphatase activity, indicating that Dolpp1p is an essential component of the brain enzyme. The presence of a consensus lipid phosphatase motif within the amino acid sequence and the observations that overexpression of *DOLPP1* in yeast and COS cells produces dramatic increases in the level of Dol-P-P phosphatase activity strongly suggest that Dolpp1p contains the catalytic site. Whether other components may be needed for full activity is a question that will only be

answered upon successful solubilization, isolation, and reconstitution of the recombinant enzyme in active form.

Although the effects of mutations in the *CWH8* gene on protein *N*-glycosylation, lipid intermediate synthesis, and the accumulation of Dol-P-P are consistent with the yeast enzyme being located in the ER, these observations are only indirect support for this conclusion. The immunofluorescence microscopy and subcellular fractionation studies described in this chapter represent the first direct evidence that Dolpp1p is located in the ER in COS cells. In addition, protease sensitivity studies indicate that the mammalian Dol-P-P phosphatase has a critical domain that is lumenally oriented. It is clear from these studies that the *DOLPP1* gene product is predominantly localized in the ER, the site of lipid intermediate biosynthesis, and protein *N*-glycosylation.

The specificity, location in the ER, and lumenally oriented active site of Dolpp1p meet all the criteria for a role in the recycling of Dol-P-P released during primary protein *N*-glycosylation reactions on the luminal surface. There is substantial evidence that cellular levels of Dol-P are a rate-controlling factor in the regulation of lipid intermediate biosynthesis (Harford *et al.* 1977; Lucas *et al.* 1977; Harford *et al.* 1980; Spiro *et al.* 1986). The induction of *cis*-isoprenyltransferase activity correlates closely with the onset of developmental increases in Dol-P and Glc₃Man₉GlcNAc₂-P-P-Dol biosynthesis, suggesting that *de novo* synthesis is an important source of Dol-P for lipid intermediate synthesis (Crick *et al.* 1994a; Crick *et al.* 1994b). However, considering the impressive effect (~80% reduction in Glc₃Man₉GlcNAc₂-P-P-Dol synthesis) produced by mutations in *CWH8* (van

Berkel *et al.* 1999; Fernandez *et al.* 2001), it seems likely that recycling of Dol-P-P plays an important role in maintaining Dol-P supplies for Glc₃Man₉GlcNAc₂-P-P-Dol biosynthesis.

The decrease in Dolpp1p activity in PPT1 knockout mouse brain suggests there is possible co-regulation of PPT1 and DOLPP1. These preliminary results prepared on a single set of samples would have to be repeated to be meaningful. Because PPT1 and DOLPP1 are localized in different subcellular compartments (lysosome vs. ER), it is impossible that the two proteins physically interact. Then, it has been shown PPT1 did not interact with any other proteins co-expressed from cDNA library derived from human cerebellum *in vivo* using the two-hybrid system (Cottone *et al.* 2001).

CHAPTER FOUR

Lipid linked oligosaccharide (LLO) accumulation in mouse models of neuronal ceroid lipofuscinosis (NCL)

4.1 Introduction

As stated earlier, the neuronal ceroid lipofuscinoses are a group of lysosomal storage disorders characterized by the accumulation of autofluorescent storage material in the brain and other tissues (Mitchison *et al.* 2001; Hofmann 2002). Although vigorous efforts have been made in the last a couple of decades, the underlying basis for the neurodegeneration is still unknown. Previously, abnormally high levels of dolichol pyrophosphoryl oligosaccharides were demonstrated in brain tissue from several NCL patients (in the era before the genetics of the NCLs were defined) but the specificity of the effect for the NCLs has been unclear.

In this chapter, I present data that lipid-linked oligosaccharide (LLO) accumulation is selective for the NCLs, with particularly striking accumulation in CLN1, CLN6 and CLN8 models using modern fluorophore assisted carbohydrate electrophoresis (FACE). The accumulated LLO in brain and liver tissues are rigorously characterized using the *CLN1/PPT1* (the most severe form of NCL) null mutant mouse model. The accumulation of dolichol pyrophosphoryl oligosaccharides is postulated to result from inhibition of late stages of lysosomal degradation of autophagosomes, which may be enriched in these metabolic precursors.

4.2 Experimental Procedures

4.2.1 Rodent tissues

Gene-targeted *CLN1/PPT1* $-/-$, *PPT2* $-/-$, and littermate control mice were maintained on a mixed C57BL/6J X 129S6/SvEv background in the animal facility of the University of Texas Southwestern Medical Center, Dallas, Texas, as described previously (Gupta *et al.* 2001; Gupta *et al.* 2003). The *CLN1/PPT1* $-/-$ and *PPT2* $-/-$ mice used in this study resulted from four to six generations of backcrosses from 129S6/SvEv onto C57BL6J. Frozen brain tissues derived from *CLN3* knockout mice (20-months of age) were a kind gift of Dr. Beverly Davidson, University of Iowa College of Medicine. Frozen brain tissues derived from *CLN2/TPPI* knockout mice (129SvEv) were a kind gift of Drs. Peter Lobel and David Sleat, University of Medicine and Dentistry of New Jersey. Mouse models of juvenile-onset NCL/*CLN3* (7-months of age, 129S6-*Cln3*^{tm1Nbm}/J, stock#: 004072), variant late-infantile NCL, *CLN6/nclf* (B6.Cg-*Cln5nclf*/J, stock#: 003605), Northern epilepsy, *CLN8/mnd* (B6.KB2-*Cln8*^{mnd}/MsrJ, stock#: 001612), Niemann-Pick Type C/*Npc1*^{spm} (C57BLKS/J-*Npc1*^{spm}/J, stock#: 002760) (Loftus *et al.* 1997), Sanfilippo Type B/*Naglu* (B6.129S6-*Naglu*^{tm1Efn}/J, stock#: 003827) (Li *et al.* 1999) and Krabbe disease/*Galc*^{twi} (B6.CE-*Galc*^{twi}/J, stock#: 000845) (Luzi *et al.* 2001) were obtained from Jackson Laboratory stocks and maintained at the University of Rochester. All of the animals were euthanized in accordance with NIH and institutional guidelines. Tissues were harvested immediately and frozen under liquid nitrogen, except tissues used for the microsomal preparation and subcellular localization studies, which were freshly prepared.

4.2.2 FACE analysis

FACE (fluorophore-assisted carbohydrate electrophoresis) analysis of LLOs derived from mouse tissues was performed essentially as described (Gao *et al.* 2002b; Gao *et al.* 2003). Briefly, tissues were homogenized in ice-cold methanol using a Polytron (Brinkmann) and dried under a stream of nitrogen. The dried pellet was extracted sequentially with chloroform/methanol 2:1(v/v), water and chloroform/methanol/water, 10:10:3 (v/v/v) (CMW). The organic phase from the final extraction was loaded onto a column containing 1 ml DEAE-cellulose (Whatman) in the acetate form equilibrated with CMW. The column was washed to remove contaminating glycogen fragments with 10 ml of CMW followed by 10 ml of CMW containing 3 mM ammonium acetate. LLOs were eluted with 10 ml of CMW containing 300 mM ammonium acetate. Chloroform (4.4 ml) and water (1.4 ml) were then added to remove ammonium acetate and the lower phase (containing LLOs) was recovered after centrifugation and dried under nitrogen gas. The oligosaccharides were released from dolichol lipid by mild acid treatment with 0.1 N HCl in 50% isopropanol for 1h at 50°C. Residual ammonium acetate was removed by desalting with Dowex (Biorad) ion exchange resins AG50-X8 (hydrogen form) and AG1-X8 (formate form). The released oligosaccharides were labeled with 150 mM ANDS (7-amino-1, 3-naphthalenedisulfonic acid, Molecular Probes) and 1 M sodium cyanoborohydride solution, and then resolved on an oligosaccharide profiling gel as described previously (Gao *et al.* 2003). The gel was imaged with a Biorad Fluor-S MultiImager using a 530DF60 filter. Electronic gel images were generated, and individual ANDS-positive species were quantified using software supplied

with the scanner. The linearity and sensitivity of oligosaccharide detection by FACE was determined with known quantities of α 1, 4-linked glucose oligomers as described previously (Gao *et al.* 2003).

4.2.3 Enzymatic digestion of ANDS-labeled oligosaccharides

ANDS-oligosaccharides were dissolved in 100 mM sodium acetate (pH 5.0) and incubated with 0.1 U per reaction (typical reaction, 50 μ l) of jack bean α -mannosidase (Glyko) or dissolved in 100 mM Na-MES (pH 6.5) containing 0.2 % Triton X-100 and incubated with 270 ng recombinant Golgi endomannosidase (a gift of Dr. Robert Spiro) at 37 °C for 18 hours. For endoglycosidase H (Endo H) digestions, ANDS-oligosaccharides (or unlabeled oligosaccharides) were incubated with 0.1 U Endo H (New England Biolabs) in 50 mM sodium citrate (pH 5.0) containing 5% glycerol and 0.1% Triton X-100 at 37°C for 30 minutes to 18 hours as indicated in the Figure Legends.

4.2.4 Microsomal preparation, LLO synthesis and oligosaccharide transfer assays

To prepare microsomes, fresh tissues from *CLN1/PPT1* $-/-$ and age-matched wild type mice were pooled (two animals from each group) and homogenized in ice-cold buffer containing 50 mM Tris-HCl (pH 7.5) and 250 mM sucrose using a motor driven Dounce homogenizer. The homogenate was centrifuged at 1,000 X g at 4 °C for 15 min to remove nuclei and cell debris. The supernatant was subjected to centrifugation at 100,000 X g at 4°C for 1 h to sediment the microsomal pellet. The microsomes were resuspended in Buffer A (50 mM K-HEPES (pH 7.5), 25 mM KCl and 5 mM MgCl₂) and incubated with 0.2 μ Ci per ml

of GDP-[2-³H] mannose, 1 μ M UDP-GlcNAc and 400 μ M acceptor peptide (Ac-Asn-Tyr-Thr-CONH₂) or control peptide (Ac-Gln-Tyr-Thr-CONH₂). The reaction mixture was incubated for 30 min at 37°C and LLOs were recovered by extraction into chloroform/methanol/water (CMW, 10:10:3, v/v/v) as described previously (Pan *et al.* 1990; Zeng *et al.* 1990; Gao *et al.* 2002b). The incorporation of [2-³H] mannose into newly-synthesized LLOs was determined by counting a portion (5 %) of the organic phase from the CMW extraction. The remaining organic phase was dried under nitrogen gas and the oligosaccharides were released by mild acid, labeled with ANDS, and analyzed by FACE as described above.

4.2.5 Isolation of autofluorescent storage material

Storage material was isolated as described previously (Palmer *et al.* 1986; Tyynela *et al.* 1993) with modifications. Briefly, *CLNI/PPT1* ^{-/-} and age-matched wild type mouse brains were homogenized in Milli-Q water using a Polytron (Brinkmann). The homogenate was filtered through glass wool and sonicated for 1 min. The resulting homogenate was centrifuged at 500 X g for 20 min and the pellet was resuspended in 16.75% CsCl (w/v, $\rho = 1.13 \text{ g/cm}^3$) and centrifuged at 1,500 X g for 20 min. The pellet was washed twice with CsCl and resuspended with Milli-Q water. The isolation was monitored visually using a Zeiss Axiophot epifluorescence microscope.

4.2.6 Differential fractionation of mouse brain tissue

Microsomes were prepared from fresh brain tissue from *CLNI/PPT1* ^{-/-} and age-matched wild type mice (two mice per group) by Dounce homogenization in sucrose buffer as described above and subjected to a series of stepwise centrifugations (1,000 X g for 10

min, 3,000 X g for 10 min, 6,000 X g for 10 min, 9,000 X g for 15 min, and 100,000 X g for 1 h). Each pellet was washed once with Buffer A and subjected to fluorescence microscopy and FACE analysis.

4.3 Results

4.3.1 LLO accumulates in *CLNI/PPT1* ^{-/-} mouse brain and peripheral tissues

Lipid linked oligosaccharides (LLOs) corresponding to the structure Glc₃Man₉GlcNAc₂-P-P-dolichol are typically the precursors of asparagine-linked glycans in mammalian cells. The steady state concentrations of LLOs are normally low in biological systems, in the range of 1 nmol/gm tissue. Fluorophore-assisted carbohydrate electrophoresis (FACE) analysis allows for the sensitive detection and structural characterization of monosaccharides and oligosaccharides in biological samples without the need for radioactive metabolic labeling (Gao *et al.* 2002b). Therefore, I applied this technique to the characterization of LLOs extracted from *CLNI/PPT1* ^{-/-} mouse tissues in collaboration with Dr. Ningguo Gao, who developed this method. Briefly, tissues were homogenized rapidly in methanol, dried under nitrogen, and the dried pellets extracted with chloroform/methanol 2:1 (vol/vol) and water sequentially to remove contaminants. The resulting pellets were extracted again with chloroform:methanol:water 10:10:3 (vol/vol/vol) to recover the LLOs, and the LLOs were treated with mild acid to cleave the pyrophosphate linkage. The released oligosaccharides were then reacted with the fluorophore 7-amino-1, 3-naphthalenedisulfonic acid (ANDS), resolved by gel electrophoresis and visualized with a fluorescence scanner (Gao *et al.* 2003).

As shown in Figure 4.1, striking accumulations of LLO intermediates were observed in brain, kidney and liver (the three tissues chosen for examination) from *CLNI/PPT1* $-/-$ mice. In brain (Figure 4.1A), the accumulation appeared to be relatively specific for LLOs migrating as $\text{Man}_{5-9}\text{GlcNAc}_2$, with little or no increase in $\text{Glc}_{1-3}\text{Man}_9\text{GlcNAc}_2$ species. In contrast, in the kidneys of *CLNI/PPT1* $-/-$ mice, all species of LLO were increased to about the same extent (Figure 4.1B). The pattern of accumulation in liver was similar to that of brain, but the accumulation was not nearly as striking (Figure 4.1C). Of note, the liver is particularly poor in storage material accumulation in different forms of Batten disease (Hofmann *et al.* 2001b).

To estimate the composition of accumulated LLOs from *CLNI/PPT1* $-/-$ and normal mouse brains, LLOs were derivatized with ANDS as described and varying amounts of labeled LLOs were loaded onto FACE gels and quantitated in comparison with known standards. Of note, the dry weight of *CLNI/PPT1* $-/-$ mouse brain (75.9 ± 4.0 mg) was 23% less than that of wild type brain (98.0 ± 5.0 mg), presumably due to massive neuronal loss during the progression of the disease (Bible *et al.* 2004). As suggested by the results in Figure 2.1D, the increase in LLOs in the *CLNI/PPT1* $-/-$ mouse brain is confined to the non-glucosylated intermediates ($\text{Man}_{5-9}\text{GlcNAc}_2$), which were accumulated to an overall level that was 14.5-fold higher as compared to wild type brain. The mature species ($\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$), which is the major species in the wild type brain, estimated at about 1 nmol per gram of dry weight, is actually decreased (to 47% of the wild type level) in *CLNI/PPT1* $-/-$ brain (asterisk in Figure 4.1).

Figure 4.1 Lipid-linked oligosaccharide intermediates (LLOs) accumulate in *CLN1/PPT1* ^{-/-} mouse tissues. (A), brain; (B), kidney; and (C), liver. LLOs were extracted and processed for fluorophore-assisted carbohydrate electrophoresis (FACE) analysis as described under *Material and Methods*. LLO standards were prepared from wild type mouse liver as described (Gao *et al.* 2002b). The positions of Glc₃Man₉GlcNAc₂-ANDS, Man₉GlcNAc₂-ANDS and Man₅GlcNAc₂-ANDS are indicated as G₃M₉, M₉, and M₅, respectively. Lane 1 and lane 2 in each panel corresponds to the ANDS-labeled LLOs from

wild type and PPT1 knockout mice, respectively. One tenth of the total derivatized extract from one organ was loaded. Results shown represent one of 3 experiments giving similar results. (D) The quantities of each ANDS-labeled LLO intermediate extracted from *CLN1/PPT1* ^{-/-} and wild type mouse brains (nmol per g dry weight) were shown. Values shown represent mean \pm S.D. (n=3). The asterisk (*) in panel D indicates that this result for Glc₃Man₉GlcNAc₂ in the PPT1 knock-out mouse was repeatable.

4.3.2 Structural characterization of LLOs from *CLN1/PPT1* ^{-/-} mouse brain

To characterize the composition and structure of LLOs that accumulate in the tissues of *CLN1/PPT1* ^{-/-} mice, several analytical enzyme treatments were performed. Jack bean α -mannosidase hydrolyzes exposed α -mannosyl residues on oligosaccharides. One or more glucosyl residues on the " α 1, 3" arm of the oligosaccharide have two effects: they block digestion of the α 1,3 arm by mannosidases, and they retard digestion of exposed mannosyl residues on the α 1,6 arm by jack bean α -mannosidase (Beeley 1985; Cacan *et al.* 2001).

Therefore, the enzyme may be used to test for the presence of glucosylated Glc₁₋₃Man₅₋₉GlcNAc₂ species. As shown in Figure 4.2A, ANDS-labeled oligosaccharides from a standard LLO mix prepared from normal mouse liver (which appears largely as Glc₃Man₉GlcNAc₂ plus various unglucosylated LLOs) was converted to the relatively protected Glc₃Man₆GlcNAc₂-ANDS (Figure 4.2A, lane 2, asterisk) and Man₁GlcNAc₂-ANDS (containing a β -mannosyl residue) as the result of digestion of the unglucosylated species (Figure 4.2A, lane 2) (Gao *et al.* 2003). The mannosyl residues most likely removed by jack bean mannosidase to generate Glc₃Man₆GlcNAc₂-ANDS are indicated in Figure 4.3 (cleavage sites labeled "a"). In contrast, all of the ANDS-labeled LLOs from the *CLN1/PPT1* ^{-/-} mouse brain were converted to a product that migrated as Man₁GlcNAc₂-

ANDS after digestion with jack bean α -mannosidase (Figure 4.2A, compare lanes 4 and 5). This result suggests that LLOs from the *CLNI/PPT1* $-/-$ brain consist of oligomers of mannose units that are not capped by glucose units.

Figure 4.2 Characterization of ANDS-labeled LLO intermediates from *CLN1/PPT1* $-/-$ mouse brain. (A) α -mannosidase and Golgi endomannosidase treatment. Glc Std, oligomerized glucose standards (G_4 through G_7). LLOs extracted from *CLN1/PPT1* $-/-$ mouse brain (lanes 4-6) and control LLOs prepared from normal mouse liver (lanes 1-3) were treated with buffer alone (lane 1 and lane 4) or were digested with either jack bean α -mannosidase (lane 2 and lane 5) or Golgi endomannosidase (lane 3 and lane 6). The asterisk (*) denotes $\text{Glc}_3\text{Man}_6\text{GlcNAc}_2\text{-ANDS}$. (B) Endo H treatment after ANDS labeling. (C) Endo H treatment before ANDS labeling. LLOs extracted from a *CLN1/PPT1* $-/-$ mouse brain (lanes 3, 4) or control Lec35.1 cells (lanes 1, 2) were treated with endoglycosidase H (Endo H) at 37°C for 30 min (B) and 18 hours (C). Subsequently, the LLOs were resolved and analyzed by FACE.

Golgi endomannosidase specifically converts $\text{Glc}_{1-3}\text{Man}_9\text{GlcNAc}_2\text{-ANDS}$ to $\text{Man}_8\text{GlcNAc}_2\text{-ANDS}$ (Figure 4.3; cleavage site marked as “b”) (Spiro *et al.* 2000; Gao *et al.* 2002b). The result of enzyme treatment of the normal mouse liver LLO mix was consistent with this specificity, shifting the glucosylated species to $\text{Man}_8\text{GlcNAc}_2\text{-ANDS}$ (Figure 4.2A, compare lanes 1 and 3) without affecting other intermediates. Treatment of LLOs from the *CLN1/PPT1* $-/-$ brain caused no changes in migration (Figure 4.2A, compare lanes 4 and 6); again suggesting that the accumulated LLO intermediates lack glucosyl residues. LLO biosynthesis occurs in a well-ordered series of reactions in which mannose residues are added sequentially to the growing oligosaccharide chain (Figure 4.3). Endoglycosidase H (Endo H) recognizes a particular mannose residue (Figure 4.3, shaded circle) that is added only after the “core” five mannose residues have been added (Figure 4.3, M_5) and then cleaves the growing chain at the $\beta_{(1\rightarrow4)}$ linkage between the two GlcNAc molecules already present on the molecule (Figure 4.3, cleavage site marked as c). Therefore, “authentic” $\text{Man}_5\text{GlcNAc}_2$ (M_5) derived from the biosynthetic pathway is insensitive to Endo H, because it does not contain the sixth mannose residue recognized by the enzyme (Figure 4.3, shaded

circle). This is illustrated in Figure 4.2B, lanes 1 and 2, in which authentic $\text{Man}_5\text{GlcNAc}_2$ prepared from CHO-K1 mutant Lec35.1 cells (which lacks a factor required for the addition of the sixth mannose) (Camp *et al.* 1993a; Anand *et al.* 2001) is shown to be resistant to Endo H treatment. In contrast, the species migrating as $\text{Man}_5\text{GlcNAc}_2$ in *CLN1/PPT1* $-/-$ brain (Figure 4.2B, lane 4) as well as the species migrating as $\text{Man}_4\text{GlcNAc}_2$ were sensitive to Endo H (lane 4). This result suggests that $\text{Man}_{4-5}\text{GlcNAc}_2$ (M_4/M_5) LLO in *CLN1/PPT1* $-/-$ brain contain the sixth mannose residue, and that rather than being “authentic” intermediates in the biosynthetic pathway, they are atypical LLOs that have gained the sixth mannose and subsequently lost residues via degradation by a catabolic pathway.

Because Endo H treatment removes the ANDS group from labeled oligosaccharides (thereby precluding an examination of the oligosaccharide products of the Endo H reaction), we performed experiments in which we incubated the LLOs with Endo H prior to ANDS labeling. In these experiments, we demonstrated that Endo H causes a shift of oligosaccharides corresponding to a loss of one GlcNAc residue (Figure 4.2C, lane 3 and lane 4), confirming the presence of the expected products of the Endo H reaction.

The absence of glucose (as indicated by α -mannosidase and endomannosidase digestion results) together with the observation of Endo H sensitivity provide strong evidence that the LLOs accumulating in *CLN1/PPT1* $-/-$ mouse brain are derived from a catabolic, rather than from the normal biosynthetic pathway.

4.3.3 LLO synthesis is normal in *CLN1/PPT1* $-/-$ mouse brain microsomes

Figure 4.3 Schematic representation of LLO intermediate synthesis in the lumen of endoplasmic reticulum (ER). Man₅GlcNAc₂-P-P-dolichol is synthesized on the cytosolic side of the ER and then flipped into the luminal side. Four more mannose units and three glucose units are sequentially added to produce the mature species Glc₃Man₉GlcNAc₂-P-P-dolichol (Helenius *et al.* 2002). Likely cleavage sites in Glc₃Man₉GlcNAc₂ for jack bean α -mannosidase (a) and Golgi endomannosidase (b) are indicated. Endoglycosidase H (Endo H) recognizes specifically 6th mannose (closed circle) added onto the “core” M₅, and cleaves the β (1 \rightarrow 4) linkage between two GlcNAc molecules (c).

To determine whether LLO synthesis proceeds normally in *CLNI/PPT1* $-/-$ mouse brain, incorporation of [2-³H]mannose into LLOs was measured using an *in vitro* quantitative assay as previously described (Gao *et al.* 2002c). Microsomal fractions were prepared from *CLNI/PPT1* $-/-$ and wild type brain and liver as described in *Material and Methods*. In short, brain (Figure 4.4A) and liver (Figure 4.4B) microsomes were incubated with 0.2 μ Ci/ml GDP-[2-³H] mannose, 1 μ M UDP-GlcNAc for 30 min at 37 °C and LLOs recovered by extraction into chloroform/methanol/water (CMW, 10:10:3). GDP-[2-³H]-

Figure 4.4 LLO synthesis in liver and brain of *CLN1/PPT1* ^{-/-} mice and age-matched wild type mice. Incorporation rate of [2-³H] mannose into LLOs was measured in normal or

CLN1/PPT1 ^{-/-} brain (A) and liver (B) microsomes in the presence of 400 μ M of acceptor or non-acceptor tripeptide for oligosaccharyltransferase. (C) % discharge of oligosaccharide intermediates onto the target peptides were calculated for brain and liver of *CLN1/PPT1* ^{-/-} and wild type mice, respectively. The results shown are typical of two independent experiments.

mannose incorporated into LLOs was counted, and assays were performed with acceptor (Ac-Asn-Tyr-Thr-CONH₂) tripeptide and non-acceptor (Ac-Gln-Tyr-Thr-CONH₂) peptides for oligosaccharyltransferase (OST) to measure the rate of discharge as well. OST is an ER luminal enzyme that transfers oligosaccharide from the mature LLO (Glc₃Man₉GlcNAc₂-P-P-dolichol) to appropriate asparagine residues of newly synthesized polypeptides. OST, however, also transfers immature LLO intermediates to the target peptide if excess acceptor peptides are available (Gao *et al.* 2002c). As shown in Figure 4.4, there were no significant differences in LLO synthesis between wild type and *CLN1/PPT1* ^{-/-} brain (A) and liver (B) microsomes.

As anticipated, liver microsomes showed higher OST activity than brain microsomes (Figure 4.4 C). However, there were no significant differences in rates of discharge of LLOs onto the target peptide between wild type and *CLN1/PPT1* ^{-/-} microsomes observed. These results suggest that LLO synthesis, extension and transfer are normal in the *CLN1/PPT1* ^{-/-} mouse.

4.3.4 Accumulated LLOs in *CLN1/PPT1* ^{-/-} mouse brain are not discharged by oligosaccharyltransferase (OST)

Figure 4.5 LLOs accumulating in *CLN1/PPT1* $-/-$ mouse are not competent for transfer to the acceptor peptide. Brain (A) and liver (B) microsomes were incubated in the presence of acceptor or control peptides for 30 min at 37°C and the extracted LLOs were resolved and analyzed by FACE. LLOs from normal brain transfer readily to the acceptor peptide (lanes

4-6) but not control peptide (lanes 1-3), whereas the LLOs specific to the PPT1 knockout tissues do not (compare lanes 7-9 and 10-12).

The experiments presented above suggest that the accumulated LLOs in *CLN1/PPT1* ^{-/-} mouse brain are catabolic products. Extracted LLOs from *CLN1/PPT1* ^{-/-} brain and liver microsomes were also analyzed by FACE after treatment with acceptor and non-acceptor peptides for oligosaccharyltransferase (OST) (Figure 4.5). LLOs in wild type brain (Figure 4.5A, lanes 1-3 vs. lanes 4-6) and liver (Figure 4.5B, lanes 1-3 vs. lanes 4-6) were efficiently discharged while almost none of accumulated LLOs in both *CLN1/PPT1* ^{-/-} brain (4.5A, lanes 7-9 and 10-12) and liver (Figure 4.5B, lanes 7-9 and 10-12) were discharged, implying that the accumulated LLOs are either not substrates for OST or that they are present in a different subcellular localization that is inaccessible to OST. As noted earlier (Camp *et al.* 1993a; Gao *et al.* 2002c), appreciable deglycosylation of pre-formed Glc₃Man₉GlcNAc₂-P-P-dolichol can occur during the incubation. This explains the predominance of Man₉GlcNAc₂-P-P-dolichol in the liver LLO samples incubated with control peptide (Figure 4.5B, lanes 1-3 and 7-9).

4.3.5 Enrichment of LLOs in autofluorescence storage material from *CLN1/PPT1* ^{-/-} mouse brain

One of the distinctive pathological characteristics of infantile Batten disease is the accumulation of autofluorescence storage material (also known as granular osmophilic deposits, or GROD) in brain and other tissues. To determine whether LLOs are enriched in this material, storage deposits were isolated by CsCl density centrifugation and analyzed by

epifluorescence microscopy (Figure 4.6A) and FACE analysis (Figure 4.6B). The crude and CsCl purified storage material were visualized under Nomarski optics (Figure 4.6A, *a* and *b*) and these images were compared with images visualized under the fluorescence microscope (Figure 4.6A, *c* and *d*). Autofluorescence in storage material purified from *CLNI/PPT1* ^{-/-} brain covered nearly 100% of the area the seen in the bright field (*b* and *d*), whereas in crude homogenates it represented a minor fraction (*a* and *c*), indicating that significant enrichment of autofluorescent material was accomplished by CsCl centrifugation. Next, LLOs were extracted directly from the CsCl purified storage material pellet and analyzed by FACE (Figure 4.6B). As a control, LLOs were extracted directly from the unfractionated *CLNI/PPT1* ^{-/-} brain (lane 4) and wild type brain subjected to the same procedures (lanes 1-3). Extracts from equivalent amounts of brain (wet weight) were loaded.

As can be seen in Figure 4.6B, most of the truncated LLOs in *CLNI/PPT1* ^{-/-} brain present in the crude homogenate (Figure 4.6B, lane 4) were recovered in the CsCl purified storage material (lane 5), indicating that accumulated LLOs are enriched in the storage material in the *CLNI/PPT1* ^{-/-} mouse (57.3-fold enrichment, see Table 4.1). Note that in normal and PPT1 defective tissue, the mature species Glc₃Man₉GlcNAc₂ was not recovered from the CsCl pellet but rather from the supernatant (compare Figure 4.6B, lanes 4 and 6 vs. lanes 1 and 3). Taken together with the results of Figure 4.5, this confirms that the accumulated LLOs in the storage material are associated with a subcellular compartment distinct from those LLOs that are utilized in asparagine-linked glycosylation. Using data similar to that presented in Figure 4.1D, we calculate that LLOs constitute 0.3% of the dry weight of storage material from *CLNI/PPT1* ^{-/-} mouse brain.

Figure 4.6 Enrichment of autofluorescent storage material and LLOs from *CLN1/PPT1* $-/-$ mouse brain by CsCl density gradient centrifugation. (A) Autofluorescent storage material was purified on a 16.75 % CsCl density gradient ($\rho = 1.13 \text{ g/cm}^3$) and the resulting pellet was resuspended in Milli-Q water. A suspension of the pellet was analyzed by epifluorescence microscopy (panels c and d), and Nomarski optics (panels a and b). (B) LLOs extracted from crude unfractionated normal brain (lane 1), the CsCl purified pellet

(lane 2) and supernatant (lane 3) were analyzed by FACE. An identical purification procedure was applied to age-matched *CLNI/PPT1* $-/-$ brain (lanes 4-6). Extracts from equivalent amounts of brain (based on wet weight) were loaded. Results shown represent one of two independent experiments yielding similar results.

Table 4.1 LLO Composition of Mouse Brain and Purified Storage

	Bodies		
	LLOs (nmol/g dry weight)		Enrichment of LLOs in Storage Bodies
	Crude	CsCl purified	
Wild type	1.2	-	-
PPT KO	19.1	1090	57.3-fold

To further elucidate the association of the LLOs with autofluorescent storage material, differential centrifugation of a homogenate of *CLNI/PPT1* $-/-$ brain was performed. Brain homogenates from *CLNI/PPT1* $-/-$ and age-matched wild type mice were centrifuged as described in Experimental Procedures and the resulting pellets were observed under Nomarski and epifluorescence microscopy (Figure 4.7A). Consistent with the known high density of the storage material, the majority of autofluorescent material sedimented at 6,000 X g or lower (Figure 4.7A, panels f, g, h), whereas the material sedimenting at higher g forces displayed little autofluorescence (Figure 4.7A, panels i and j). As shown in Figure 4.7B, the pellets from the differential centrifugation were processed and analyzed by FACE.

Figure 4.7 Co-fractionation of LLOs accumulating in *CLN1/PPT1* ^{-/-} mouse brain with autofluorescent storage material and non-ER fractions. Brain homogenates from age-matched wild type and *CLN1/PPT1* ^{-/-} brains were fractionated by differential centrifugation. (A) The fractionated homogenates from *CLN1/PPT1* ^{-/-} brain were analyzed by epifluorescence microscope (lanes f-j) and Nomarski optics (lanes a-e). (B) The resulting fractions from wild type (lanes 1-5) and *CLN1/PPT1* ^{-/-} (lanes 6-10) brains were subjected to FACE analysis. (C) An aliquot of each fraction was incubated with GDP-[2-³H] mannose for 30 min at 37 °C to monitor the extent of incorporation of [2-³H] mannose into LLOs. Results shown are one of two independent experiments yielding similar results. The asterisk (*) denotes Man₉GlcNAc₂-ANDS.

In wild type brain, the bulk of LLOs sedimented in the 100,000 X g microsomal fraction (Graham 1984) and appeared as the mature LLO, Glc₃Man₉GlcNAc₂-ANDS (Figure 4.7B, lane 5). However, in the *CLN1/PPT1* ^{-/-} brain, most of the accumulated LLOs were sedimented between 1,000 X g and 6,000 X g in fractions that were also highly enriched in autofluorescent material. As a metabolic marker for each fraction, the extent of incorporation of [2-³H] mannose into LLOs was monitored (Figure 4.7C). An aliquot of each fraction was incubated with GDP-[2-³H] mannose for 30 min at 37°C followed by CMW 10:10:3 (vol/vol/vol) extractions. A portion of the organic phase of the extract was counted to determine the rate of LLO synthesis. As expected, [2-³H] mannose incorporation into LLO was predominantly observed in the 100,000 X g fractions from wild type and *CLN1/PPT1* ^{-/-} brains, which is consistent with the known subcellular localization of LLO synthesis in the endoplasmic reticulum.

Interestingly, the major band observed in 100,000 X g pellet of *CLN1/PPT1* ^{-/-} brain was Man₉GlcNAc₂-ANDS (asterisk) rather than Glc₃Man₉GlcNAc₂-ANDS, and the level of Glc₃Man₉GlcNAc₂-ANDS was reduced as compared with wild-type. It is possible that this

was caused by deglycosylation of pre-formed $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-dolichol}$ during fractionation.

4.3.6 Age-dependent accumulation of LLOs in brains of *CLN1/PPT1* $-/-$ mice

The accumulation of LLO intermediates was age-dependent as assessed in the brains of 2-week to 6-month-old PPT1 knockout mice (Figure 4.8). Mannosylated LLO intermediates were the predominant component of the accumulation and started to accumulate as early as 2 weeks of age. Greater than 10-fold accumulation of LLOs as compared to the wild type were observed by the age of 6 months, an age at which 50 to 75% of mice develop neurological abnormalities such as claspings and myoclonic jerks (Gupta *et al.* 2001).

Figure 4.8 Accumulation of LLO intermediates in *CLN1/PPT1* $-/-$ mouse brain is age-dependent. Brains from *CLN1/PPT1* $-/-$ mice from 2 weeks to 6 months of age were analyzed by FACE. A wild type mouse brain at 6 months of age is shown for comparison

(lane 1). Each lane represents 10% of one whole brain. The result shown is one of two yielding similar results.

4.3.7 Accumulation of LLO intermediates in mouse models of lysosomal storage disease (LSD)

In each case, brains from at least three clearly symptomatic animals were examined and representative results are shown. (Of note, all mouse models represent complete loss of function mutations, with the exception of the *CLN6/nclf*, and *CLN8/mnd*; in these two models, the impact of underlying missense mutations on protein function is unknown.) Marked LLO accumulation was observed in the brains of *CLN1/PPT1*^{-/-} (Figure 4.9A, lane 2), *CLN6*^{-/-} (lane 8) and *CLN8*^{-/-} (Figure 4.9B, lane 8) mice. These models have all been shown to demonstrate copious amounts of autofluorescent storage material in brain tissue (Bronson *et al.* 1993; Bronson *et al.* 1998; Ranta *et al.* 1999; Gupta *et al.* 2001; Bolivar *et al.* 2002 ; Gao *et al.* 2002a; Wheeler *et al.* 2002). Lesser but significantly increased LLOs were seen in *CLN2*^{-/-} (Figure 4.9C, lane 2), and *CLN3*^{-/-} (Figure 4.9A, lane 6) mouse brains. Accumulation of LLOs in *PPT2* knockout mice was modest (Figure 4.9B, lane 10) consistent with the scant amounts of storage material in brains of mice at this age (Gupta *et al.* 2003). Quantitation of LLOs by densitometric scanning of gels in comparison with standards revealed that brains from symptomatic mice with Niemann Pick type C (NPC), Sanfilippo syndrome type B (NAGLU) and Krabbe disease (GALC) were not significantly different from normal (Figure 4.9D). These results, taken together with the demonstration of LLOs in the autofluorescent storage material of *PPT/CLN1* mice, support a relative specificity for LLO accumulation in the neuronal ceroid lipofuscinosis.

Table 4.2 Characteristics of NCL mouse mutants in this study

Disorder	Defective gene	Affected protein	Mouse phenotype	Age at this study	Ref.
Infantile NCL	<i>CLN1/Ppt1</i>	Palmitoyl protein thioesterase-1	Spasticity by age 5 months. Myoclonic jerking and seizures. Fatal by 10 months.	7-mo	(Gupta <i>et al.</i> 2001; Gupta <i>et al.</i> 2003)
Late Infantile NCL	<i>CLN2/Tpp1</i>	Tripeptidyl peptidase-I	Tremor at 7 weeks and then ataxia, median survival 4.5 months.	3.5 to 4-mo	<i>a</i>
Juvenile NCL	<i>CLN3</i>	Lysosomal transmembrane protein	Neuropathological abnormalities. Motor coordination deficits at 6 months.	6-mo and 20-mo	(Mitschison <i>et al.</i> 1999), <i>b</i>
Variant Late-Infantile NCL	<i>CLN6(Nclf)</i>	Putative transmembrane protein	Progressive retinal atrophy. Gait disturbance and weakness in limbs evident by 6 months and severe paralysis by 9 months.	6-mo	(Bronson <i>et al.</i> 1998; Gao <i>et al.</i> 2002a; Wheeler <i>et al.</i> 2002)
Epilepsy with mental retardation	<i>CLN8(Mnd)</i>	Putative transmembrane protein	Hindlimb weakness and ataxia at 6 to 7 months. Behavioral abnormalities.	7-mo	(Bronson <i>et al.</i> 1993; Ranta <i>et al.</i> 1999; Bolivar <i>et al.</i> 2002)
Unknown	<i>PPT2</i>	Palmitoyl protein thioesterase 2	Spasticity and ataxia by 13 mo. Scant neuronal storage. Bone marrow infiltration and extramedullary hematopoiesis. Death by 17 mo.	14-mo	(Gupta <i>et al.</i> 2003)

^aSleat, D.E. and Lobel, P., unpublished data.^bWeimer, J. M. and Pearce, D. A., unpublished data.

LLO profiles of five homozygous NCL mouse models (*CLN1/PPT1*^{-/-}, *CLN2/TPPI*^{-/-}, *CLN3*^{-/-}, *CLN6/ncf*, and *CLN8/mnd*), three non-NCL models (Niemann Pick Type C, designated *NPC*^{-/-}, Sanfilippo Type B, *NAGLU*^{-/-}, and Krabbe disease, *GALC*^{-/-}) and the *PPT2*^{-/-} mouse were analyzed by FACE (Figure 4.9).

The characteristics of the animal models and the ages of mice used in the experiment are summarized in Tables 4.2 and 4.3.

Table 4.3 Characteristics of non-NCL LSD mouse mutants in this study

Disorder	Defective gene	Affected protein	Mouse phenotype	Age at this study	Ref.
Niemann-Pick Type C	<i>NPCI</i>	Transmembrane protein with sterol-sensing domain	Weight loss, tremor and ataxia by 7 wks.	2-mo	(Miyawaki <i>et al.</i> 1982; Loftus <i>et al.</i> 1997; Patel <i>et al.</i> 1999)
Sanfilippo Type B	<i>NAGLU</i>	α -N-acetyl-glucosaminidase	Ganglioside accumulation in brain. Heparan sulfate in liver and kidney. Death at 8 to 12 mo.	9-mo	(Li <i>et al.</i> 1999)
Krabbe Disease	<i>GALC</i>	Galactocerebrosidase	Normal at birth. Progressive tremor, weakness and wasting at 3-wk. Death at 3 mo.	1-mo	(Duchen <i>et al.</i> 1980; Luzi <i>et al.</i> 2001; Biswas <i>et al.</i> 2002)

Figure 4.9 LLO profiles of brain tissue from mouse models of NCL and non-NCL lysosomal storage disorders. All mice demonstrated overt neurological signs at the time of analysis, with the exception of 7 month old CLN3 $-/-$ mice, which are shown for comparison. Three representative gels (A, B, and C) are shown. Lanes represent paired wild-type littermate controls (odd lanes) and mouse models (even lanes) as indicated. The mouse models analyzed and their corresponding human disorders are CLN1/PPT1 $-/-$ (infantile NCL), CLN3 $-/-$ (juvenile NCL), CLN6/*nclf* (variant late infantile), NPC $-/-$ (Niemann-Pick Type C), NAGLU (Sanfilippo B), GALC (Krabbe disease), CLN8/*mnd* (Northern epilepsy), and PPT2 $-/-$ (unknown). In Figure 2.9C, lane 1, only heterozygous littermate controls were available for analysis (designated +/-). Each lane represents 10% of a single whole brain. Three brains from each model (and an equal number of littermate controls) were analyzed. (D) Quantitation of LLO profiles determined by densitometric scanning of FACE gels. Values shown represent mean \pm standard error of the mean.

4.4 Discussion

In the present study, a 15-fold elevation of lipid-linked oligosaccharide (LLO) intermediates was demonstrated in the brains (and lesser increases in other tissues) of mice representing models of neuronal ceroid lipofuscinosis. The LLOs represent intermediates in a catabolic pathway, as determined by structural characterization through enzymatic digestion and FACE analysis. The rate of incorporation of [^3H] mannose into new LLO synthesis in brain and liver microsomes of *CLN1/PPT1* $-/-$ mice was normal, as was the rate of oligosaccharide discharge from LLO to an oligosaccharyltransferase acceptor peptide, again supporting the idea that the accumulation of LLOs is related to a defect in LLO degradation rather than synthesis or transfer. Excess LLOs co-localized with autofluorescent CsCl purified storage material from *CLN1/PPT1* $-/-$ mouse brain and sedimented in the heavy lysosome-like fraction rather than the microsomal fraction. Quantitative analysis showed that the LLOs constituted only a minor proportion of the autofluorescent storage material (0.3 %) by mass. The accumulation of LLOs was age-dependent and specific for mouse models of

NCL (CLN1, CLN2, CLN3, CLN 6 and CLN8) and not seen in three mouse models of other lysosomal storage disorders (Niemann Pick type C, Sanfilippo syndrome type B, and Krabbe disease).

In several respects, I have confirmed and extended earlier studies performed on brain material obtained at autopsy from NCL patients in the era before NCL genetics were defined. The quantitation of LLOs in the storage material measured in brain tissue from human (Daniel *et al.* 1992) and mouse (this study) were remarkably similar (13.7 nmol/g vs. 17.2 ± 1.4 nmol/g and 2.1 ± 1.9 nmol/g vs. 1.2 ± 0.7 nmol/g for infantile NCL/CLN1 and normal brain, respectively). The dolichol-phosphate content measured in two infantile NCL brain samples (0.3 and 0.37% by mass) (Hall *et al.* 1989) agree well with our estimation of LLO from CsCl purified storage material from CLN1 mouse brain (0.3%). The results in this chapter confirm that LLO does not constitute a major portion of the mass of the material.

The structural characterization of LLOs in mouse CLN1 brain was also consistent with experiments performed by others (Daniel *et al.* 1992; Hall *et al.* 1992) and support the conclusion that these LLOs represent catabolic rather than synthetic intermediates. In this study, I was, in addition, able to cleanly separate the abnormal catabolic products from the normal synthetic products by differential centrifugation, with the catabolic intermediates pelleting in the dense fraction and the normal intermediates fractionating as expected in the 100,000 X g microsomal fraction.

In a previous studies, no differences in incorporation of [^3H]-mannose or oligosaccharidyl transferase (OST) activity were found in cells derived from JNCL as compared to control cells (Hall *et al.* 1992; Van Dessel *et al.* 1992). The results in this

chapter have confirmed the normal incorporation of [^3H] mannose into brain and liver microsomes prepared from CLN1 mice. In addition, it has been shown that there was no block in transfer of the oligosaccharide from dolichol-PP to nascent protein, because the discharge rate of LLOs onto an acceptor peptide was normal. Thus, the failure to transfer as a mechanism for accumulation of LLO is ruled out in this form of NCL.

Why might catabolic LLOs accumulate in NCL tissues? Any model must account for the appearance of LLOs in the dense fraction, the complete absence of glucosyl residues, and the partial loss of mannosyl residues. A potential explanation for the appearance of LLOs in dense membranes may be autophagocytosis. The lipofuscin pigments and residual storage bodies observed in NCL have structural properties reminiscent of autophagolysosomes, sometimes containing clear morphological evidence of partially autolyzed mitochondria or other organelles. These 'tertiary lysosomes' are believed to form from the fusion of autophagosomes and mature lysosomes as a late step in the process of autophagy (Dunn 1990; Cuervo *et al.* 1998; Kim *et al.* 2000). In the NCLs, the metabolism or removal of these autophagolysosomes appears to be inhibited. Although the origin of autophagocytic membrane is not yet clear (Dunn 1990; Klionsky *et al.* 2000), it has been suggested that the formation of autophagic vacuoles is initiated from the membranes of rough endoplasmic reticulum (RER) (Dunn 1990) which is also the site of LLO synthesis and transfer to proteins. Therefore, it is likely that 'catabolic' LLOs accumulating in NCLs are derived from autophagocytic membranes, and that the accumulation of LLO in the NCLs may result from their over-representation in membranes (such as RER) destined for autophagocytic removal. An alternative explanation may be that a small fraction of the LLO pool is always missorted

to lysosomes and rapidly degraded. However, due to a lysosomal dysfunction in NCL (see below) these LLOs would accumulate as storage material.

Degradation of $\text{Man}_9\text{GlcNAc}_2\text{-P-P-dolichol}$ would normally be expected to be carried out by lysosomal α -mannosidase, a housekeeping enzyme. The optimal physiological pH for lysosomal α -mannosidase is 4.5 (Merkle *et al.* 1997; Stinchi *et al.* 1999). However, it has been reported that lysosomal pH in fibroblasts derived from NCLs is elevated by as much as 1 pH unit (Holopainen *et al.* 2001). Perhaps the lysosomal pH is insufficient to ensure complete degradation of LLOs at this step. Alternatively, it is possible that the $\text{Man}_5\text{-}_9\text{GlcNAc}_2\text{-P-P-dolichol}$ forms aggregates, or are in some other way inaccessible to lysosomal α -mannosidase. It is also plausible that one of the other storage products (for example, in the case of PPT1 a palmitoylated peptide) acts as a mannosidase inhibitor.

The absence of glucosyl residues from the accumulated LLOs in PPT1 defective tissue may simply indicate that deglucosylation occurs efficiently in the dense membranes. Alternatively, for some reason the LLOs in dense membranes may be selectively derived from non-glucosylated LLOs generated from the pool of $\text{Man}_9\text{GlcNAc}_2\text{-P-P-dolichol}$ that is normally present in equilibrium with $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-dolichol}$ as a result of the glucosyltransferase-glucosidase shuttle in the ER (Spiro *et al.* 1991).

CHAPTER FIVE

Conclusions and Future Directions

In this dissertation, I have cloned and characterized *pdf1*, an ortholog of *PPT1* in *S. pombe*, by ablating the gene and determining the consequences of inactivating mutations in the Ppt1p and Dolpp1p domains independently through plasmid complementation assays. It was demonstrated that *pdf1* ablation causes lethality, and that Dolpp1p alone can rescue the lethal phenotype. It was also shown that cells containing no functional copy of Ppt1p are abnormally sensitive to sodium orthovanadate and elevated external pH, which are phenotypes associated with vacuolar dysfunction in yeast. Furthermore, I have demonstrated that Pdf1p in *S. pombe* expressed as a single polypeptide with the orthologs of human *PPT1* and mouse *DOLPPI*. However, these two proteins are post-translationally processed into two independent proteins. By immunoblotting yeast extracts with antibodies that recognize the carboxyl terminus of Pdf1p, I have provided evidence that Pdf1p is produced as a precursor protein that is cleaved to two separate polypeptides, probably as a result of a kex-related protease, Krp1. Finally, it has been shown that a human *PPT1* cDNA is able to complement the phenotypes of Ppt1p deficiency, demonstrating that *S. pombe* provides a new genetic model for the study of Batten disease.

I have also cloned mouse *DOLPPI* gene from a mouse brain cDNA library, which encodes a dolichol pyrophosphatase 1. The mouse *DOLPPI* has been confirmed to complement the defects in growth and protein *N*-glycosylation, and to correct the accumulation of Dol-P-P in the *cwh8Δ* yeast mutant. Northern blot analysis has demonstrated

a wide distribution of the *DOLPPI* mRNA in mouse tissues. In COS cells, overexpression of Dolpp1p has produced substantial increases in Dol-P-P phosphatase activity but not in dolichyl monophosphate or phosphatidic acid phosphatase activities in microsomal fractions. Subcellular fractionation and immunofluorescence studies have localized the enzyme encoded by *DOLPPI* to the endoplasmic reticulum of COS cells. The results of protease sensitivity studies with microsomal vesicles from the *lpp1* Δ /*dpp1* Δ yeast mutant expressing *DOLPPI* are consistent with Dolpp1p having a lumenally oriented active site. The sequence of the *DOLPPI* cDNA predicts a polypeptide with 238 amino acids, and a new polypeptide corresponding to 27 kDa has been observed when *DOLPPI* is expressed in COS cells. I have presented the first identification and characterization of a cDNA clone encoding an essential component of a mammalian lipid pyrophosphate phosphatase that is highly specific for Dol-P-P.

Finally I have examined brain and tissue samples from the five well-defined genetic mouse models of the NCLs and other mouse models of lysosomal storage disorders with central nervous system neurodegenerative phenotypes using a newly developed fluorophore-assisted carbohydrate electrophoresis (FACE) technique to analyze the characteristics of the LLO in these well-defined specimens. I have confirmed that LLO accumulate to high levels in five types of NCL but not in three non-NCL lysosomal storage disorders. I have characterized these in detail in *CLN1/PPT1*^{-/-} mice. There was an age-dependent accumulation of LLO, which are highly enriched in storage material yet constitute only a small fraction (0.3%) of its mass. Detailed structural characterization revealed that the LLO

are consistent with catabolic products, and the increase in LLOs in the *CLN1/PPT1* $-/-$ mouse brain is confined to non-glucosylated intermediates ($\text{Man}_5\text{-}_9\text{GlcNAc}_2$).

In conclusion, the data presented in this dissertation describe that Ppt1p and Dolpp1p are functioning as independent polypeptides, and no direct interaction between the two is evident in higher eukaryotic cells. Although the gene structure of *pdf1* in *S. pombe* suggested a certain degree of interaction between Ppt1p and Dolpp1p, it was demonstrated that the two proteins are processed post-translationally and probably localized in different compartments. Furthermore, subcellular localization studies of mouse Dolpp1p demonstrated that Dolpp1p is localized in the ER membrane (PPT1 is a soluble lysosomal enzyme). Therefore, it is less likely that these two proteins are physically interacting in higher eukaryotic cells. Finally, the analysis of the accumulation of lipid linked oligosaccharides (LLOs) in infantile NCL using PPT1 knockout mouse model has revealed that those LLOs are the accumulation of ‘catabolic’ products rather than that of ‘metabolic’ intermediates, which might be caused by defects in dolichol recycling. Therefore, it is more likely that the abnormal dolichol metabolism in infantile NCL results as a secondary phenotype of lysosomal dysfunction triggered by PPT1 deficiency, rather than an effect directly from Dolpp1p function.

Future studies into the molecular mechanisms of infantile NCL could address several interesting questions. First, how do LLOs accumulate in the storage material during the neuropathogenesis of infantile NCL? As I discussed earlier, it would be worthwhile to investigate whether autophagy plays a role during the development of the disorder. Mouse embryonic fibroblasts (MEF) from PPT1 null mutant mice are an important tool for this kind of studies. It will be interesting to see whether LLOs accumulate in autophagic vacuoles that

are induced by vinblastine or other drugs that blocks autophagy in wild type and the PPT1 deficient cells.

Are LLOs substrates for Dolpp1p? And is Dolpp1p activity normal in PPT1 deficient tissues? Preliminary data have shown that Dolpp1p activity in PPT1 deficient mouse brain was reduced. The assays should be repeated to provide a more definitive answer for these questions. One improvement that could be made would be to separate out the catabolic LLOs (in the non-ER, lysosomal fraction) from the microsomal fraction by differential centrifugation. In this way, possible interference by the accumulated LLOs can be prevented during the enzyme assay for Dolpp1p activity.

Another question is what are the direct, physiological substrates of PPT1 *in vivo*? PPT1 deficiency should lead to the accumulation of acylated peptides in the lysosomes of affected brain tissues. It has been shown that [³⁵S] cysteine-labeled lipid thioesters derived from fatty acylated proteins accumulate in lymphoblastoid cells derived from infantile NCL patients (Lu *et al.* 1996). These metabolically radio-labeled lipids from PPT1-deficient infantile NCL lymphoblastoid cells are separated as five distinctive bands by high-performance thin layer chromatography (TLC). These infantile NCL specific bands are associated with the dense lysosomal fraction and the accumulation of these infantile NCL specific thioesters are corrected by incubating the patient's lymphoblastoid cells with recombinant PPT1 in prior to the metabolic labeling (Lu *et al.* 1996; Lu *et al.* 2002).

There have been attempts to purify those infantile NCL specific, metabolically radio-labeled thioesters from the patient's cells. However, the efforts are not fruitful so far mainly because the mass of the accumulated thioesters in the cells is too low. The storage material

accumulated in infantile NCL is extremely heterogeneous. Furthermore, the major component of the storage material has not yet been elucidated. As I have demonstrated, accumulated LLOs constitute only a minor portion (0.3% by mass) of the autofluorescent storage material in the PPT1 deficient mouse. Therefore, in order to identify the physiological substrate for PPT1, it is necessary to use a method that can specifically separate the substrate from the heterogeneous, hydrophobic storage material. One possibility is to use of biotin-streptavidin system. Biotinylated-HPDP (hexyl-3'-(2'pyridyldithio-propionamide)) can be useful because HPDP is able to react with the thiol groups in the putative PPT1 substrates (acylated small peptides) in the storage material (Jaffrey *et al.* 2001a; Jaffrey *et al.* 2001b). If this works, the molecule trapped by biotin-streptavidin will be identified by mass spectrometry.

I have shown that the mutations on dibasic motifs in the linker domain of *pdf1*, the *S. pombe* ortholog of PPT1, completely impair the posttranslational processing. Another question that remains to be answered is how impairment of the post-translational processing affects the function of *pdf1*. So, it will be interesting to see whether this impairment affects the function of Ppt1p and Dolpp1p individually. The preliminary observation was that the cells harboring the double mutants (R344A, R354A) were significantly growth retarded compared to the cells harboring wild type plasmid. It would be also interesting to see whether the PPT active site mutants and the processing mutants cause any LLO accumulation in *S. pombe*. LLO profiling by FACE analysis in yeast has not been reported and it would be worthwhile to verify the profile of LLO intermediates in these mutants.

I have shown that the *S. pombe* system can be used as a model organism for infantile NCL. To further extend the benefit of this lower eukaryotic model system, it will be necessary to construct mutant strains that have PPT active site mutations integrated into the chromosomal allele. Once these mutant strains are constructed, then suppressor screening can be done by transforming human cDNA library to discover human gene(s) that complement the vacuolar dysfunction phenotypes of *S. pombe*. The analysis of suppressor genes may provide a clue as to the mechanism of infantile NCL.

There are many gaps to be filled understanding how PPT1 deficiency leads to neurodegeneration in affected children. I have valuable information that can be used to fill these gaps. However, more pieces are required to solve this puzzle. That effort will lead to a better understanding of the neuropathogenesis of infantile NCL and will eventually elucidate the molecular mechanisms of infantile NCL.

Vitae

Steve Kyungrae Cho was born in Busan, Korea, on September 4th, 1968, the first son of Dr. In Jae Cho and Mrs. Jung Soon Cho. After graduating from Young Dong High School in Seoul, Korea in 1987, he entered Han Yang University in Seoul, Korea. After completing the first two years of college, in 1989, he decided to pursue his education further in the United States. He received the degree of Bachelor of Science with a major in Biochemistry from University of California at Los Angeles in June, 1994. During his senior year, he joined the laboratory of Dr. H. Philip Koeffler at UCLA School of Medicine (Division of Hematology-Oncology, Cedars-Sinai Medical Center) as a student research fellow. After receiving his B.S. degree, he continued to work as a research associate in Dr. Koeffler's lab for two more years. In August, 1996, he entered the Graduate School of Biomedical Sciences at the University of Texas Southwestern Medical Center at Dallas. After one year of study at the division of cell and molecular biology, he joined the laboratory of Dr. Sandra Hofmann, a professor of Internal Medicine and Molecular Genetics, for his dissertation work and received the Ph.D. degree in August 2004. In 1996, he married to Judy Cho and they have two children, Timothy and Rachel. Timothy was born in April 1997 and Rachel was born in September 2001.

Permanent Address: 9220 Forest Hills Drive, Irving, TX 75063

This dissertation was typed by Steve K. Cho.
